This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

Usage guidelines

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

+ *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.

+ *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.

+ *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.

+ *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at `http://books.google.com/`

INDEX.

Abortion, Concerning Treatment of, 239, 635.
Early. 383, 780.
Abrasions of the Skin, 741.
Abscess, 274.
Absolute Alcohol in Erysipelas, 230.
Absorption of Iron, 24.
Of Odors by Milk, 496.
Abdominal Tumors, 120, 442.
Contusions, A Practical Study of Serious, with a Clinical Report of Twenty-one Cases, Thomas H. Manly, M D., 745, 781, 858, 893.
Surgery—A Group of Cases Covering Almost the Entire Field of, M. Price, M.D , 444, 498.
Section for Traumatism, Robert G. Le Conte, M D., 716, 733.
Sections for Pelvic Ailments, J. W. Brainerd, M.D., 685
Abortive Treatment of Gonorrhœa by Permanganate of Potash, 526.
Abuse of Milk in Treatment of Albuminuria, 346.
Accidents from Electric Currents of Great Intensity, 473
Acne, 651.
Vulgaris, Nature and Treatment of, 164.
Acute Yellow Atrophy of the Liver, 801.
Addisonian Intoxication, 236.
Adenoid Growth in the Dome of the Naso-Pharyngeal Space, J Morrison Ray, M.D., 74
Discussion, 120
Advice as to Stimulants, 664.
Affections of the Eyes in Relation to Gynecology and Obstetrics, 491.
Alcohol, 655.
In shock, 742.
Alcoholism, Treatment by Strychnine Nitrate, 130.
Alimentation in Pulmonary Disease, 224.
Alterations of the Urinary Stream, 541.
"Americanism" in Modern Medicine, German View of, 760.
Amputation at the Hip-Joint, Bloodless Gradual Dissection Method, 200.
Of Thigh, Fracture of Humerus, Sarcoma of Chest, Tubercular Lymph, Nodes, Roswell Park, A.M., M.D., 568
Anal Fistula, Treatment of, J. McFadden Easton, M.D., 467.
Ancient Use of Sterilized Water, 595.
Anemia in Diseases of the Respiratory Passages, 572.
Anesthesia by Cocain Deprived of its Disadvantages by Trinitrine, 707.
Anesthetics in Labor, 286.
Aneurism of the Aorta, New and Distinguishing Sign of Latent, 228
Angina from Copaiba Balsam, 667.
Animal Parasites which We Obtain Through Our Food, 295.
An Old Medical Protest Against Railroad Trains, 632.
Antitoxic Action of the Liver, 780.
Anterior Poliomyelitis, Acute, 666.
Antiseptic Dressing of the Umbilical Stump, Hiram Corson, M D., 423.
Treatment of Diseases of the Stomach and Intestine, 507.
Properties of Oil of Cinnamon, 131.
Antipyrin in Painful Affections of the Bladder and Prostate, 214.
As a Vesical Analgesic, 779.
As a Sedative in Prostatic Hypertrophy, 238.
Antidote to Potassium Cyanide, 220.
To Hydrocyanic Acid, 360.
Anthrax in Man, 346.
Apocynum Cannabium in Heart Diseases, 360, 741.
Appendicitis, Rational Treatment of, 486, 727.
Continued Discussion of, 264.
Clinic Report of Four Cases of, 373.
131, 198, 670.
Report of a Case, Francis A. Webb, M.D., 606.
And Peri-Appendicitis, 152.
Arsenic in Recurrent Herpes, 237.
Arterial Catheterism, 671.
Artificial Feeding and the Care of Infants, John W. S. McCullough, M.D , 138.
Artresia Vaginæ, 338.
Aseptic Vaccination, 526.
Asparagus, Action of, on the Kidneys, 562.
Ataxic Paraplegia, A Case of, Theodore Diller, M.D., 796.
Atmosphere and Life, 701.
Atonic Gastric Dilatation, Treatment of, 344.
Authentic Report of the Assassination, Operation and Death of Carnot, the President of the French Republic, Prof. A. Poncet, 149.
Auto-Infection, 776.
Auxiliary Treatment of Syphilis, 155.

Bacteriology in Midwifery and Prophylaxis of Puerperal Fevers, W. P. Gamber, M.D., 97
Bacilli Tuberculosis in Cigars, 132
Bathing in Typhoid Fever, An Easy Method of, 189.
Benzoate of Sodium, 330.
Beri Beri, 230.
Bicycle-Riding for Women, 740.
Biliary Calculi, 640
Bismuth Subgallate or Digestive Ferments? 595.
Bits of Natural History, 653.
Blood in Melancholia, 165
In the Secretion of the Mammary Gland, 489.
Serum Therapy; Its Evolution and Present Status, 197.
Board of Charities and Correction—of Medicine, The, 871.
Boiled Milk as an Aliment Abroad, 779.

have served their ends in the animal economy.

Chlorophyl, by giving, as it were, specific direction to the vibrations which constitute solar light and heat, tears asunder the atoms of O and C in the compound CO_2 and of O and H in H_2O, freeing O while the remaining elements are appropriated by the plant in the formation of carbohydrates and other compounds capable of reoxidation. Hæmoglobin, on the other hand, supplies oxygen, breaks up the carbohydrates and other oxidizable compounds and forms CO_2 and H_2O.

Electricity, magnetism and chemism are closely related forces, if indeed they be not different modes of manifestation of essentially the same force. They all have the same ultimate basis in the capacity of matter for molecular polarization. Each may be developed by another, each converted into another. The special office of magnetism is to effect transmutations of force.

Most of the elements may be arranged into an electro-chemical series with the alkali metals, potassium, sodium, etc., with hydrogen at the positive, and the halogans, chlorine, bromine, etc., with oxygen at the negative end. Occupying a space in the middle of the series are the metals, iron, manganese and chromium. These metals present a strong resemblance in the variety in color of their oxides and salts, their behavior toward oxygen, their magnetic properties and the fact that they may occupy either the acid or basic side of salts. It is by reason of their position in the electro-chemical series, possessing as they do affinities in opposite directions, that the condition of bipolarity may be readily induced in them and they are hence distinctively magnetic. They are sometimes found on one side of the middle line manifesting acid or negative affinities, sometimes on the other manifesting basic or positive affinities, their difference in behavior depending upon special conditions in the different cases.

The coloring matters chlorophyl and hæmoglobin, by virtue of the iron which exists in them in the magnetic condition, possess the property of polarity. Furthermore, in a state of physiological activity, they are constantly undergoing reversals of affinities or poles. This probably involves a true mechanical, molecular motion, the molecules of chlorophyl and hæmoglobin serving as a mounting so to speak, for the atoms or particles of magnetic iron, and allowing their rotation by the adjustment of their own atoms. Magnetism is dynamic, that is, capable of producing effects, mechanical, electrical or chemical, only when the body in which the magnetic condition exists, or that upon which it acts, is in a state of *motion;* or the magnetism itself is varying, commencing, increasing, diminishing or ceasing, in which case the molecules themselves of the magnetic substance may be inferred to be in a state of motion. Its special office in nature, as observed before, is the transmutation of other forces, changing their directions so to speak, and specializing their activities. A permanent magnet may be viewed as a static condition of force, motion come to rest, yet embodying a capacity to take up motion and convert it into other modes of force.

The property of two-endedness, of right and left-handedness, though difficult to reduce to a distinct mechanical conception, pertains to light and heat as to the other physical forces. Their capacity for polarization, the reduction to definite planes and directions of the vibrations which constitute the essential nature of these forces, indicates their relation to the other polar forces. Faraday has shown that a ray of polarized light or heat may be deflected from its course by subjecting it to the influence of a magnet.

The color green, occupying as it does the middle of the solar spectrum, is interesting in this connection as an index to the capacity which chlorophyl possesses of abstracting the middle constituent, dividing the solar ray, and giving to the vibrations above and below green in the chromatic scale specific directions by virtue of which they polarize and set in motion the atoms of the magnetic metal, iron, contained in the chlorophyl. The magnetization of the the iron with motion superadded, develops electro-chemical force. The condition of polarity and motion induced in the iron is a transitional condition of the force which is received on the one hand as vibratory motion and delivered on the other as electro-chemical force.

This electro-chemical force is expended in tearing apart the atoms of O and C in the compound CO_2 and of O and H in H_2O and becomes posited as it were in the atoms of O on the one hand and of C and

H on the other, to be again delivered up as heat, mechanical motion, muscular activity, etc., when these atoms again meet at the other border of the organic world. This attractive force of the atoms of C and H in the hydrocarbonaceous compounds formed for the displaced oxygen, is the exact equivalent and complement of the solar energy used in parting them and constitutes the ultimate basis of all force manifestation in organic life.

Plants, utilizing the energy of solar light and heat, manufacture out of materials drawn from the atmosphere and taken up from the soil by the roots, a variety of compounds, starch, fats, albumen, etc. A part of these compounds fall from the elevated plane of "proximate principles" to the condition of simple binary compounds, the measure of which retrograde metamorphosis is the amount of CO_2 exhaled by the plant. This descent from a higher to a lower plane liberates force which in conjunction with external heat and acting through the agency of diastase and perhaps other catalytic agents more or less closely related to chlorophyl, lifts another part of these compounds to the grade of organized vegetable tissue. The greater part, however, remains as reserve stores of material and force, to be either used by the plant itself in the construction of parts subsequently developed, or to serve as food for animals.

Animals receive ready prepared for them in the vegetable kingdom, the materials for their structure embodying the capacities for the force evolutions which constitute the expressions of life. True, much of this material is raised to much higher planes, substances of exceeding complexity, of high molecular weight, being required to meet the demands of the extreme differentiation of form and function in the higher orders of animal life. In this lifting of pabulum for the formation and maintainance of organic structure force is consumed, contributed no doubt by the retrograde metamorphosis of other constituents of the food, but rendered available through the agency of so called ferments. Some of these are, in all probability, products of the ductless glands and as yet but little known.

The great and striking characteristic of animal life however, as distinguished from vegetable life, lies in the fact that its chemical processes are, in the main, reductions of matter with evolution of force, which finds expression as heat, sensori-motor force, etc. These reduction processes and force liberations are accomplished through the agency of hæmoglobin and its derivatives, the coloring matters of bile and urine. At the top of the scale of organic nature, we find beginning processes the exact reverse and complements of those we found initiated by solar energy through the agency of chlorophyl in the green leaves of plants. These processes end in the complete restoration to inorganic nature of the matter and forces which have performed their parts in the mystic play of that inscrutable something we call life.

The red corpuscles of the blood, by virtue of the iron which exists in them in some sort of union with their hæmoglobin, take up oxygen from the air in the lungs and deliver it up in the capillary circulation, returning with their hæmoglobin in the reduced condition. In making the circuit from the lungs, through the capillaries and back to the lungs, the hæmoglobin changes from the bright red of highest oxygenation to the violet of lowest reduction, passing no doubt through the whole gamut of colors. When it leaves the lungs, it occupies the red or dynamic end, when it returns to the lungs, the violet or chemical end of the chromatic scale, its color at each stage of the declension being the index to its dynamic capacity. At the point of lowest reduction, its dynamic capacity is a minimum, its chemical affinity for oxygen, after it reaches the lungs, a maximum. At the point of highest oxygenation, its chemical affinity for oxygen is satisfied, its dynamic capacity a maximum. At the opposite extreme of the circuit, this chemico-dynamic force, of which the hæmoglobin in its transit is the vehicle, is reconverted into heat and motion by the impact, as it were, of atoms which had been torn apart by the dynamolytic action of chlorophyl in the green leaves of plants.

Chlorophyl and hæmoglobin, with the other catalytic agencies between them, require for the physiological activity certain necessary conditions. One of these is always heat or equivalent force in the ascending constructive, lifting force consuming series on the one hand; another, the presence of oxygen with its capacity of unlocking force in the descending, destructive force releasing series on the

other. Solar force, either as the direct rays of the sun or as diffused daylight is necessary, furnishing as it does the *vis agendi* for the activity of chlorophyl. This activity, with the processes which depend upon it, ceases in the dark. The permanent withdrawal of light *starves* green-leaved plants to death. It has, however, been experimentally shown that plants will flourish in the electric light which is, after all, but a reproduction of the sun's rays.

Diastase could never imitate and carry forward the process of germination in seeds without the proper degree of *heat*. Heat is also just as necessary for the germination of an egg as for the sprouting of a seed.

The nature and mode of operation of the various substances which serve to transmute heat into constructive energy under the directive agency of animal and vegetable organisms, appear to me to furnish a rich field for study and practical experimentation.

The alkalinity of the blood and tissues furnishes an all-important condition for the activity of hæmoglobin in the animal economy. The alkalinity of the blood differs at the two extremes of the circuit. In the lungs, it reaches its highest degree because of the exhalation of carbonic acid. In the capillary circulation, it becomes less alkaline from the absorption of carbonic acid. In passing from the lungs to the capillaries, hæmoglobin crosses its equator between acid and basic affinities. In returning to the lungs, it recrosses to its region of positive attractions. In the lungs it is electro-positive and unites with oxygen, which is electro-negative. In the capillaries of the various organs and tissues of the body, it becomes electro-negative, repelling the oxygen.

As regards the effect on oxygen, it is essentially an ozonizing process, in which the atoms of O_2, the ordinary condition of oxygen, are disassociated and polarized in the same direction. In this condition they cannot unite with each other though possessing in the highest degree the affinities of oxygen.

It would seem, however, that the alkalinity of the blood, with its changes in degree at the extremes of the circuit, does not absolutely *endow* hæmogoblin with its polarity, or cause of itself alone the reversals of affinities. Blood outside the body will for a time manifest this property, as evidenced by its changes in color from red to purple or purple to red, according as oxygen is excluded or supplied. Even hæmogoblin if extracted unchanged from fresh blood will manifest this property.

An examination into the rationale of the guiacum test for blood shows that even the hæmatin of old blood stains possesses a remnant of this property, inasmuch as it is able to convert the antozone of peroxide of hydrogen into ozone. The basis for the property is beyond question in the essential nature of the iron which is contained. It is well known that a certain oxide of iron manifests, like the black oxide of manganese which has an analogous formula, catalytic activity. This peculiar form of activity, when traced to its ultimate nature, will be found to lie in the capacity of these substances for taking on and giving off oxygen, which capacity is itself dependent upon the magnetic nature of the metals, iron and manganese. When black oxide of manganese is mixed with chlorate of potash in the familiar process of preparing oxygen for laboratory purposes, there is needed but the proper degree of heat, molecular motion, to start or accelerate the revolutions of a multitude of molecular magnets, by which electro-chemical force is generated, which tears the oxygen from its combination in chlorate of potash and gives it off in the free state.

The alkalinity of the blood, however, with its changes in degree at the extremes of the circuit, is necessary to the performance of the physiological function of the red corpuscles, by determining the time and place at which the reversals of the oxygen affinities of hæmogoblin occur, causing them to occur at the opportune moment in each case. In the lungs, where alone oxygen is obtainable, the highest oxygen affinity of hæmogoblin is thereby developed. In the capillaries of the various organs and tissues of the body, where oxygen is needed to meet the demands of the ceaseless change, the highest repulsive force of hæmogoblin for oxygen is thus brought into action.

When the blood-cells die, their hæmoglobin undergoes a conversion into a substance which has been called hæmatoidin, the more complex molecule of the former breaking up and the atoms of C, H, N and O, rearranging themselves into

the simpler molecules of the latter. The iron and sulphur are released and, in part, perhaps reappropriated by young cells, and in part used up in the growth of the horny tissues, hair, nails, etc.

This substance, hæmatoidin, is believed to be identical with bilirubin, the yellow-red coloring matter of bile. Bilirubin has been found in old extravasations of blood evidently produced upon the spot by transformation of hæmoglobin. If red blood-cells be broken up and made to assume a liquid form by alternate freezing and thawing, and the solution injected into the veins of an animal, the operation is followed by a discharge of bilirubin in the urine. Under ordinary conditions, the liver extracts the coloring-matter from the blood-cells as fast as they die, completing their disintegration. Under other conditions, as the introduction into the circulation of certain poisons, or a depraved condition of general nutrition, the cells may die more rapidly than the liver can dispose of their coloring-matter, and jaundice of the hæmotogenous variety occurs, with yellow discoloration of the skin and mucous membranes, and great increase of coloring-matter in the urine.

In phosphorus poisoning, oxygen is abstracted from the blood-cells with such rapidity and to such extent that they are disorganized in great numbers, and this variety of jaundice with ecchemoses, hemorrhages, etc., supervene. In hemorrhagic malarial fever, we have the usual phenomena attendant upon rapid destruction of blood-cells and liberation of coloring-matter. In cirrhosis of the liver, a disease in which this function which the liver has of separating the coloring-matter from dead corpuscles, is interfered with by pressure upon the liver-cells and disturbed circulation, we may have some degree of jaundice and always have increase of coloring-matter in the urine.

With ordinary obstructive jaundice, which results from reabsorption of bile, we are not concerned in this paper.

The coloring-matter of bile exists in *two conditions,* bilirubin and biliverdin, the red and the green matter of bile. The difference between them is one of hydration and oxygenation, biliverdin being derived from bilirubin by the assumption of a molecule of water and an extra atom of oxygen; bilorubin from biliverdin by reversing the process.

Bilorubin Biloverdin

$$C_{16}H_{18}N_2O_3+H_2O+O=C_{16}H_{20}N_2O_5$$

Experiments have shown that bile drawn directly from the bile ducts *during digestion* is green, though reddish-brown when drawn from the gall bladder. If reddish-brown bile be shaken up with air, or exposed to the action of an oxidizing agent as nitric acid or iodine, its color changes to green. Then if oxygen be excluded by placing it in a bottle and corking tightly, the green changes to reddish-brown again. Bilirubin preëxists in the worn-out and dead corpuscles from which it is extracted by the liver, undergoing, however, an immediate conversion into biliverdin while digestion and absorption are in progress. The coloring-matter of bile, in its two conditions of bilirubin and biliverdin, occupies a place midway in the scale between the red coloring-matter of blood and the green coloring-matter of plants, and performs functions related to that of each, taking part in the vegetative processes of nutrition on the one hand, and the oxidations of animal life on the other.

Glucose, $C_6H_{12}O_6$, the product of the digestion of starch and saccharine substances is absorbed from the intestine by the radicles of the portal vein and conveyed to the liver where it is deposited in the form of glycogen or liver starch $C_6H_{10}O_5$, to be again given off in the form of glucose as required for the needs of the system. In the process of being deposited in the liver, glucose undergoes a dehydration into glycogen; in the process of being given off, glycogen undergoes a hydration into glucose.

It is also known that albuminose, the product of the digestion of the albuminous elements of the food, undergoes a reduction in the liver into blood albumin, losing an atom of oxygen. The dehydration of glucose into glycogen and the deoxidation of albuminose into blood albumin are accomplished by the presence of bilirubin which, at the instant of its extraction from the dead corpuscles, undergoes a conversion into biliverdin, appropriating a molecule of water from the glucose and an atom of oxygen from the albuminose. The liver-cells by a selective action upon the glucose and albuminose of the portal vein upon the one hand, and the coloring-matter of worn-out corpuscles upon the other, brings

these substances into intimate relation with each other, effecting the interchange between them of water and oxygen, converting glucose into glycogen, albuminose into blood albumin, bilirubin into biliverdin.

During the intervals of digestion, quite a different circle of events takes place. During digestion, the blood is receiving more glucose from the intestine than is required for the needs of the system, and there is a surplus which is reduced to the form of glycogen, as we have seen, and stored in the liver for future use. Soon after absorption is completed, however, the liver completes its work of reducing glucose to glycogen, and begins instead to give off its glycogen as glucose. Whereas, in the first place, some agency was required to reduce glucose to glycogen, we now need some means to raise glycogen to glucose. This means is supplied again by the accommodating coloring-matter.* There is abundant evidence that the bile continues to be secreted during the intervals of digestion, that it is always present in the intestine, that it is of a reddish-brown color, its coloring-matter being in the condition of bilirubin, and that it is, for the most part, reabsorbed.

Under the changed condition of things, the bile continuing to find its way into the empty intestine, is absorbed into the portal and its bilirubin by the assumption of oxygen from the red corpuscles and water from the plasma of the blood, undergoes a conversion into biliverdin. This biliverdin, when it reënters the liver comes in contact with the glycogen and yields up to it its water, becoming reconverted into bilirubin and reconverting the glycogen into glucose, thus rendering it again diffusible when it is swept off into circulation. The atom of oxygen associated with the molecule of water in the biliverdin and liberated with it, is no doubt applied to the final oxidation of nitrogenous substances which have served their ends in the economy, of which reaction the urea found in the liver is the product.

The liver may be regarded as a chemico-vital laboratory in which certain elements of the food are prepared for assimilation, while other substances which have yielded up their capacity for meeting the demands of structure and function are prepared for elimination. In this laboratory the reagent effecting the changes is the coloring-matter, acting under the same conditions of heat and oxygen supply which are necessary for the activity of other allied substances above and before it in the scale.

COMMUNICATIONS.

CHLORAL HYDRATE—SOME OF ITS USES.†

BEN. H. BRODNAX, M. D., Brodnax, Louisiana.

In conversation with physicians at various times, I have noticed they viewed chloral as merely a hypnotic, and had used it only for the purpose of relieving pain, thereby inducing sleep. I have been a little surprised at this want of knowledge of its other equally valuable properties. Early in my practice I tried to make a few medicines, combined or by themselves, do all that they would for me, and was led into experimentation with them. Chloral came in for its share, because it relieved pain, quieted the nervous system, and did not paralyze the bowels.

As a *hypnotic,* five grains of chloral combined with laudanum or with one-eighth or one-quarter grain of morphine acts splendidly, the combination intensifying the effects of each and depriving the opiate of its stimulating property. With children by itself, in sweetened water, it has no equal ; mixed with paregoric, it is also good.

I *prepare* it as follows : I just cover the amount in my case vial with glycerin—this dissolves it, and a drop is about a drain. In this form it mixes readily with oil or water and is more quickly prepared, and more easily divided into doses, large or small. With castor oil the dose one to

*The liver's work of breaking up dead corpuscles goes on, notwithstanding the necessity as well as the conditions for forming *green* bile have ceased.

†Read before the Philadelphia County Medica Society by Oscar H. Allis, June 13, 1894.

five grains renders it less nauseating, and does not grip, at the same time producing quiet and rest.

Applied to the skin in eruptive diseases —measles, urticaria—as follows: chloral, 10 drains (drops); carbolic acid, 10 grains (drops); water or oil, 1 to 2 ounces, almost instant relief is experienced of the intense itchings. Or chloral, 10 drops; glycerin and water, each ½ ounces, produces the same effect.

As a mouth-wash: Chloral, 10 grains; glycerin and water, each ½ ounce (a teaspoonful), produces a pleasant cool sensation in salivation, or as a gargle. After holding it for a moment in the mouth it should be rejected and an equal amount of the fresh solution may be swallowed. Carbolic acid (10 drops) added, makes it more effective in ulceration of the mucous coverings. It seems to act on the nerves locally, the same as chloroform by inhalation does on the body.

In toothache: Chloral, camphor, glycerin, carbolic acid, equal quantities, applied on a small piece of cotton after cleaning the cavity will relieve the pain. (Cover with more cotton to fill the cavity). I keep the mixture, ready made, under the name of "Toothache drops," in my medicine case. If the patient has lost sleep I give a full dose of chloral by the mouth.

For ulcerated sore-throat, or ulceration from any cause, such as scalds: Chloral, 10 to 15 drops (grains); water, 1 to 2 ounces, as to age; sugar, to make it palatable to children, a teaspoonful, repeated at short intervals until sleep is induced, then on waking to keep them fully under its influence. My first experience was on my only daughter, four years old. The case was so severe I feared I would lose her, and to get rest for her, gave as above, after having tried everything else I knew of. The almost immediate relief of all the bad symptoms led me to think the medicine acted *otherwise than merely as a rest-producer*. Since then, for ten years I have used it with the utmost satisfaction to myself and patients.

Earache: Camphor, 10 grains; chloral, 10 grains; carbolic acid, 10 grains; castor oil, ½ ounce. Drop into the ear warm. Fill the ear full, apply a piece of cotton wet in warm water to fill the external ear, then a cloth wrong out in hot water as warm as can be borne. I have seen some almost crazy children go to sleep in two or three minutes and awake free of their troubles.

As an aid to chloroform in surgery or obstetrics, 10 to 15 grains, given twenty minutes before administration of the anæsthetic, seems to intensify the effect and less than one-half of it is needed to produce the desired effect. In my obstetric practice for the last fifteen years I have used it, and have observed but one case where any unpleasant effects were induced. This was a woman with her tenth child. I gave the choral to relax the system, 10 grains; in half an hour 5 grains more; in half an hour the chloroform. It affected her almost immediately and the child advanced and came away in good style, but the woman seemed to be dead drunk and incapable of moving herself. She slept soundly for several hours and awoke all right. She was conscious and would answer questions, but could not use herself. This was the first time she had taken either of the drugs, and she may have been susceptible—easily affected. Chloral, given before the anæsthetic, seems to tide them over the excited stage of anæsthesia. The first few whiffs of the anæsthetic produce quiet without any excitement. I have used it in a few surgical cases with the same effect. In children a full dose of chloral, and when sleep comes on they are anæsthetized in that state, and the force often necessary, otherwise, is avoided.

In coryza, where the Schneidering membrane is very irritable, chloral, 10 grains (or drops); castor oil, ½ ounce, used with a soft mop, applied over the surface, after being dried, acts to check the excretion of mucous, and lulls the irritation and the head-pains.

The supposed influence of the drug on the heart has been urged by my friends against its use. I have not seen any unpleasant effects. In any case where there is a chance of any cordiac trouble, it is an easy matter to fortify the heart with a $\frac{1}{50}$ gr. of nitroglycerin. In one delicate woman I did this as a precaution, but even in her case I believe it was not necessary. This summarizes my experience with chloral, and when I tell you I use from five to six pounds a year, you may know that it has a very considerable scope. I never prescribe it in any quantities, so as to create a "habit." In fact, I do not know of a single case of the kind.

RECTAL ABSCESS.*

J. M. MATHEWS, M. D.,† Louisville, Ky.

I have chosen as a theme for a short paper to-night a subject which may appear at first glance too insignificant for your consideration, but I am sure that it demands serious thought from a surgical standpoint.

It is for the very reason that too little consideration is given abscesses in a general way, and rectal abscesses in a special way, that I desire to bring the subject before the Society this evening. It has been my misfortune to see one patient die from the effects of a rectal abscess, and several others barely rescued from a fatal result from the same cause. It is the common, too common, observation of the surgeon who sees much rectal practice, that abscesses in this region are treated by the physician in a very unsurgical way. Indeed, it seems to be the common practice to instruct those in charge of such cases to avoid all means looking to an early evacuation of pus, but on the contrary to allow nature to do the work of evacuation. In other words, to poultice the threatening abscess until it bursts. From such advice I have seen more than a score of patients that not only had run the risk of sepsis, but had been made invalids for life. If there is one surgical precept that should be taught in preponderance above another, it is, that pus should be evacuated as soon as discovered. Indeed, I believe that the surgeon is justified often in cutting down upon this inflammatory tumor when he *suspects* pus, but has no positive evidence of its presence. I would rather cut into such a tumor and find no pus than to allow an ounce of it to remain in the tissues twenty-four hours. This rule holds good whether the abscess be a cold or hot one, whether it is due to acute conditions or can be traced to a special diathesis, as tubercular, etc. I could not imagine a case better suited to bring discredit upon the physician, or to form a basis for a malpractice suit, than to allow an abscess to burrow for days or weeks, as is often done, around and through the tissues of the rectum. If a patient escapes constitutional infection he runs the risk of such local destruction as will make him an invalid for life. Recognizing, then, the necessity for an early evacuation of rectal abscesses, I have only to call your attention to the manner that is usually practiced in opening them. I believe that you will bear me out in saying that the common practice, even with reputable physicians, is to *puncture* these abscesses. It does seem that men, who would not hesitate to amputate an arm or leg, will not only hesitate about opening abscesses around the rectum, but when they do so the smallest instrument possible is used for the purpose. Many patients have told me that a needle was used by the physician for the purpose; and if a knife was used, it was one with the most delicate blade.

In this connection you will permit me to refer to a few cases that I have now under observation:

Case 1. A young lady, aged twenty-three, was brought to me several weeks ago from a Southern state, giving the following history: About eighteen months ago she gave symptoms of a rectal abscess. A physician saw her, and so pronounced her trouble. The swelling was great, and the pain nearly unbearable. She begged that the abscess be lanced, but her physician informed her that it was not *ripe*, and that she must wait. Three weeks' time was consumed in this waiting, and at last nature accomplished her work and the abscess *broke*. Of course poulticing was kept up both before the bursting of the abscess and after. After inflammatory action had subsided the doctor proceeded to treat the fistulous condition, which of course resulted. An injection plan was inaugurated, iodine, carbolic acid, etc., being the agents that were thrown or injected into the sinuses every few days. The result of this treatment was that a second abscess resulted, this time in the other buttock. This too, was allowed to *take its course*. After she recovered from the second abscess she refused further treatment, and came to me. You can very well imagine the condition in which

*Read before the Louisville Clinical Society, Feb. 27, 1894.

†Professor of Surgery, Clinical Lecturer on Diseases of the Rectum, Kentucky School of Medicine.

I found her. A young girl only twenty-three years of age, handsome, prepossessing, and otherwise healthy, crippled beyond measure by this bad and ill-advised treatment. Upon examination I found on one side two external openings, which led into fistulous sinuses, measuring six to eight inches in length, and running in different directions. On the other side I found the buttock entirely riddled with sinuses, cavities, etc., and communicating with the bowel at great depth. The operation necessary to cure this girl required the most extensive wounds and a three months' stay at the Infirmary. The sphincter muscle being the objective point, it required the most careful surgery to preserve it.

Case 2. A young man, aged twenty-four, came to me from a distance. Upon examination I found a large, patulous, indolent ulceration around the rectum. The finger could be run into a cavity fully four inches, and under the flaps of skin to a distance of two inches in different directions. He gave the history of a cold abscess, and the condition I saw was plainly tuberculous. I advised an immediate operation, which consisted in the complete removal by knife, scissors and curette of all tuberculous tissue.

The recital of these two cases will be sufficient for me to base a few remarks upon in regard to the treatment.

There are two things that should be scrupulously followed by the physician having in charge a patient suffering from rectal abscess, viz., early evacuation of pus and free drainage.

Considering the great percentage of cases of this kind that end in fistula, it is the duty of the surgeon to prevent that calamity, and the time to do it is while treating the abscess, which is always the forerunner of the latter. Considering, too, the local ravages that both abscess and fistula make, it is little less than criminal to allow such to occur when the prevention can be so easily practiced. To the layman or the uneducated doctor it may seem preposterous to propose that a patient suffering from a rectal abscess should be chloroformed and operated on, but to the surgeon of experience or a pathological student it would appear eminently proper. In every case of rectal abscess I would suggest the following plan of treatment:

Just as soon as pus is detected, or the surgeon has good reason to suppose that it is present, the patient should be informed of the necessity of a free lancing of the abscess to avoid sepsis or fistula in ano.

Having administered a purgative, and the parts thoroughly cleansed, the anæsthetic should be given, and with a large knife a free incision should be made into the structures. This, of course, causes a free evacuation of pus. An irrigator should be ready with a 1 to 5,000 mercuric solution, and the cavity thoroughly washed with the same. The surgeon's finger should now be introduced into the abscess cavity, and all bridges, loculi, etc., broken down, when a free injection of peroxide of hydrogen should be practiced. A dilator should now be inserted into the rectum and the spincter muscle freely divulsed. Iodoform gauze should now be introduced well into the cavity, cotton applied, and a T bandage, and the patient put to bed. On the second day these dressings should be removed and the cavity syringed by sol. mercuric or peroxide of hydrogen, and gauze inserted as before. This should be kept up each succeeding day until the cavity has closed and wound healed. No poultices of any kind should be allowed to be applied after the abscess has been opened.

It can be definitely asserted that if this course is pursued in cases of rectal abscess, fistula in ano would become one of the most infrequent of rectal affections, whereas, now, it is claimed by some to be the most frequent. It will be noticed that I have suggested the free divulsion of the sphincter muscle while operating for the abscess. This is done in order that the spasm which naturally affects the muscle during the existence of an abscess be done away with. The contracting of the muscle inordinately at this time would prevent good union, when by resting it everything is made quiescent.

The injunction not to use poultices after lancing can be appreciated by all antiseptic surgeons. If heat is necessary, hot sterilized cloths can be used; however, the tension being relieved by the cut, but little pain is afterward suffered. The old idea was that by poulticing a free discharge of pus was secured, and that pus was so necessary in those days to the healing of wounds.

NEW METHODS EMPLOYED FOR THE RELIEF OF IMPAIRED HEARING, ESPECIALLY BY THE USE OF THE PHONOGRAPH, VIBROMETER, VIBROPHONE, AND METRONOMIC EAR MASSEUR.*

LOUIS J. LAUTENBACH, M. D., PH.D., PHILADELPHIA.†

I present this short paper in order to direct attention to a comparatively new way of treating the ear, with a view of restoring or benefiting defective hearing, and dissipating tinnitus.

Contrary to former beliefs, hearing is not to any great extent dependent upon the integrity of the drum-head, but rather upon the preservation of the proper relationship of the various parts of the sound-conducting apparatus. It is now known that if the external meatus be clear and the auditory nerve intact, not only may the membrane be perforated but even extensively destroyed, provided the chain of bones be normal and in perfect adaptation, the hearing will be perfect. To illustrate this, I call attention to a case I treated in 1883. In a case of long-standing suppuration with extensive granulations, I succeeded, upon the careful and complete removal of the granulations, and the subsequent subsidence of the middle-ear inflammation, in retaining Shrapnell's membrane, with the chain of bones, in perfect position. The consequence was that the hearing for the voice, as well as metallic sounds, became perfect and has so remained.

Perfect hearing depends then upon the exact balance of the ossicles one to the other, and to their proper relationship to the oval window and drum-head, between which they are suspended. If any or all of these parts are abnormal in any way—as, for instance, as to the weight of one or more of the bones, or if there be any abnormal attachment between the ossicles, or between the stapes and oval window, or any attachment of the drum-head to the inner wall of the middle ear—there will be derangement of that nicety of adjustment, that perfect balance which is necessary to good hearing.

The membrana tympani may be considered as little more than the outer fixation point of the ossicles—as a protector for the middle ear, in small part, aids the hearing by concentrating all sounds and upon the short process of the malleus.

Seeing the necessity for perfect freedom of motion in this sound-conducting apparatus, we can readily understand the importance of preventing or, should such exist, removing any attachments of these bones to each other or to the surrounding parts. Any effusions upon them—effusions even if unattended by the formation of attachments—may occasion over-weighting of some of these delicate bones, and thus interfere with the proper conductibility of sound. Should these unfortunate conditions occur, we then have impaired hearing, and usually a greater or less degree of tinnitus.

Numerous operations and methods of treatment have been devised for these cases. They aim either to restore the parts to a normal condition, or to conduct the sound directly to the oval and round windows without the intervention of the ossicles. This latter was accomplished either by perforations or destruction of the drum-head, or the removal of one or more of the ossicles, with or without the drum-head. Since Schwartze first removed the drum-head and malleus in 1873, until the present, operations on the ossicles have become more and more frequent, until recently we find one writer reporting some 300 cases of these operations in about two years. Most operators remove the drum-head with one or more of the ossicles, but Jack removes the stapes alone without the drum-head, evidently reasoning that as ankylosis exists almost always at the juncture of the stirrup in the oval window, by thus removing the stapes the sounds will be carried directly to the membrane of the vestibule. I have performed excision with the removal of one or more of the ossicles but twenty-three times. I, however, do not think it should be resorted

*Read before the Philadelphia County Medical Society, May 23, 1894.

†Surgeon to the Pennsylvania Eye and Ear Infirmary; nose and throat physician to the Odd Fellows' Home; late chief of the eye clinic of the German Hospital, etc.

to until all other methods to restore mobility have failed. In future I intend to perform it only in such cases as, where after prolonged, careful treatment, especially after the thorough use of the instruments I will show you to-night, I fail to relieve distressing tinnitus or very defective hearing. I will then perform it only as a last resort, as when the ossicles are gone and there is no improvement, there is much probability of future help.

Massage methods, or methods to break up adhesions within the middle ear, may be said to date from the time that Guyot reported the invention of the Eustachian catheter to the Paris Academy in 1724. He not only opened the Eustachian tube, thus relieving the tension of the membrane and ossicles, but forced air through it into the middle ear, thus forcing the membrane and ossicles back into their normal position, loosening or breaking any attachments that had been formed. The methods of Valsalva and Pliotzer were but applications of Guyot's idea, their object being the same.

It is, however, not of these methods which operate through the Eustachian tube, but of such methods as exert their beneficial action by increasing and diminishing pressure on the membrane and chain of bones, through the external meatus, to which I will call your attention to-night.

Massage methods as applied to the ear can be separated into phono-massage, the massage occasioned by sounds; pneumo-massage, that occasioned by the condensation and rarefaction of air in the meatus; pressure-massage, where direct pressure is applied to the membrane or ossicles, and mixed massage, a combination of pneumo- and phono-massage.

Probably the first method employed to produce massage was by means of the open hand, so adapted to the ear as to produce a suction effect, alternately pushing and removing it with a slightly sliding motion. This method, as well as the one of opening and closing the meatus by the use of finger, as we often see swimmers do, was undoubtedly practised by the ancients.

Cleland in 1771, recommended the sucking of air from the external meatus for therapeutic purposes, but it was later forgotten until Moos brought the method of rarefaction of air in the external meatus again into use as a means of treatment. A method formerly employed was by means of the suction of a syringe, with an olive-shaped tip. The tip having been adjusted to the meatus, the piston was drawn back, and, by means of the vacuum produced, the membrane was drawn outward; hemorrhage and even rupture of the membrane was often thus occasioned.

The first scientific instrument to accomplish massage, the Siegle otoscope or pneumatic ear speculum, was presented to the profession in 1864. This instrument was followed by the fungoid-shaped balloon of Lucae, and the rarefacteur and masseur of Delstanche. Siegle's otoscope consisted of an air-tight ear speculum closed without by a glass plate, and connected with a tube to which a mouth-piece was attached. By inserting the speculum the membrane could be examined and its movability determined by motion of the mouth. By alternate suction and condensation, massage was accomplished. Lennox Browne improved the instrument by substituting a rubber bulb in place of the mouth-piece, Delstanche substituted a small double-valved air-pump, and then called it the rarefacteur. Later, Delstanche used a tube, inserted into the meatus, and produced rarefaction and condensation by means of a small hand-pump, capable of regulation, calling this the masseur; but in this instrument he omitted the speculum and thus was unable to see just what effect he was producing. Lucae about this time began to use massage directly on the short process of the malleus by means of this elastic pressure sound, alternately pressing and relieving the tension.

In 1884 Sexton used double ear tubes as a method of education of those suffering with defective hearing, apparently unconscious that he was on the threshold of an important discovery. It is of this instrument that Spear said: "It was invaluable to stimulate the auditory nerve whose functions have become impaired by disuse." It remained for Currier to discover that, not only was it a good teaching method, but that the hearing often improved. These were, so far as I know, the first applications of phono-massage.

In 1887 Maloney presented the otophone to the public. This was nothing more than a speaking-tube closed at one end by a diaphragm. He used it not only as a speaking-tube, but also as a method of im-

proving the hearing, by means of the massage it effected on the drum-head and ossicles.

In 1891 Garcey commenced to use the phonograph to improve the hearing; he was followed by Leech and Houghton. Instead of using the ordinary records, they used cylinders with lines made not by sound, but graved more or less deeply. In 1893 McFarlane used the phonograph, with the ordinary cylinders, for the same purpose.

In 1892 Garcey commenced to use a string instrument—the sounds made by the vibrations of the strings of a banjo being conducted to the ears—which he called the vibrometer. This instrument has been very much improved of late, and now consists of four strings stretched over a banjo-frame. The strings are set in vibration by a pronged wheel which, as it revolves over them picks the strings, the sounds being carried to the ear by the ordinary double ear tubes. One string can be thus played, or two strings may be kept in vibration. In addition to this, the instrument is provided with a suction apparatus. There is a diaphragm in an air-tight cavity within the banjo-head, which is moved up and down by the motion of an eccentric on the shaft, and connected with this cavity is a pair of double ear tubes. You are supposed in this way to be able to obtain simple massage, but as a matter of fact there is a great deal of noise traveling into the ears as long as the machine is in motion.

The vibrophone is an instrument introduced last year, the purpose of which is to carry to the ear the sounds of a rapid or slow interrupter of an induction circuit, as well as to produce, at the same time, a distinct change in the air pressure on the drum-head. As originally constituted, it carried sound only, but has been modified as above at my suggestion.

Wilson has used the telephone for the production of ear massage. Semrock has used the tuning-fork for the same purpose. Hundreds of others have experimented with the tuning-fork in the same direction.

Before describing my own apparatus, I will briefly refer to the methods mentioned. The old mechanical methods of applying massage by the hand produced good effects but were crude. Cleland's and Moos's methods labor under the same disadvantage. The Siegle speculum, the rarefacteur and masseur are all of value, but they cannot be continued as long as many cases demand, nor can they be as carefully regulated as desirable. Sexton's conversation tubes are of value, as is likewise Maloney's otophone, but they are conductors of sound and sound vibrations, and while they independently of this yet produce motion of the membrane and ossicles, this is not capable of exact regulation, nor is there any way of using massage without the sound. This same objection holds also so far as the vibrometer and vibrophone are concerned; neither of them gives massage without sound, although the vibrometer is supposed to answer these requirements.

It seems reasonable to suppose that in some of these cases of defective hearing associated with more or less immobility of the sound-conducting apparatus, the auditory nerve may be exhausted or diseased. We find it so in mill hands and in boiler and sheet-iron workers; their auditory nerves become at first over-stimulated, and later exhausted. In treating such cases, as well as in hyperæsthetic conditions of the auditory nerve, as little sound as possible should be transmitted for fear of occasioning further damage. To treat such cases I found silent or simple pneumo-massage was required. To accomplish this, I constructed a machine in which I had a slow and fast interruptor in connection with an induction coil, and connected with this was an air-tight telephone with a double ear-tube. Each make and break of the current causes a to-and-fro motion of the telephone diaphragm, and this occasions a corresponding motion of the ear drum. Later, I began to use instead of my induction coil interruptors, a metronome to make and break the current, and find it better in every respect. With it I can produce anywhere between forty and two hundred and eight to-and-fro motions of the drum membrane per minute, the amplitude of motion being dependent upon the size of the diaphragm and strength of current, both of which I can regulate. I have called this instrument the metronomic ear masseur.

For some two months I have been experimenting with the phonograph, both as an ear-test and as a remedial agent. For the former purpose I have found it the most accurate and the best test I have

at my command. As a remedial agent, especially for the application of phono-massage, I have found it very valuable. For this purpose I use voice and instrumental records as well as mechanical records. By this I mean records that have been produced by cross-lining the cylinders, or regularly grooving with lines parallel to the axis of the cylinder (making the lines on some cylinders deep, on others shallow; on some close together, on others far apart).

The work with the phonograph has not progressed sufficiently far to allow me to speak as to its true scientific value. I can only say that it has, in my hands, proven to be by far the best phono-massage instrument I have employed, as sounds of any desired pitch or quality, and practically of any required volume, can be thus obtained.

To illustrate the effects of these new instruments (I refer especially to the vibrometer, vibrophone, phonograph, and the metronomic ear masseur) I will present to you but a few of the one hundred and fifty-three patients that I have treated by this method; two of these patients I have here this evening.

In order to disarm those who would contend that the improvement in hearing was in no wise connected with the massage treatment, I would say that I treated some thirteen patients by this method alone with universally good results; and out of some twenty-eight patients whom I had treated in the ordinary manner, without improvement, but on the addition of massage to the previous treatment all but three improved.

In presenting to the State Medical Society a paper on this subject, I classified my cases as follows: Series I. Those who had been treated by me without improvement, and who improved upon the addition of massage treatment. Series II. Those treated by massage alone—all improved. Series III. Those treated by the combination of massage treatment with ordinary local and constitutional measures. Series IV. Deaf-mutes—two cases only, both improved. Series V. Those treated by usual measures with addition of massage without appreciable benefit; of these there were but six in the 153 cases.

I will narrate but one case of each class.

SERIES I., Case 3.—Mr. C. Z., aged seventy-seven years, treated by me in 1884 for eight months; no marked improvement. He has been affected since 1869. He returned to me March 27, 1894, membranes very much thickened with lower half adherent to promontory; watch not heard in either ear, conversation not heard; only hears upon being talked to in ear, and then only with great difficulty. For the past year or two, unable to distinguish the piano tones; has been an expert pianist. After daily treatment for twenty days he informed his friends of his improved hearing, and remarked that for the past two days he can again enjoy the piano, being able to distinguish the tones.

SERIES II., Case 9.—Mr. J. S. S., aged sixty-five years, came March 19, 1894, with great loss of hearing and tinnitus, extending over a period of twelve years—voice-hearing poor. Watch: right ear, three inches; left ear, hard contact. Two treatments a week for three weeks gave him marked improvement of voice-hearing; with watch-hearing, right and left ears, of seven and five inches respectively; tinnitus heard only occasionally.

SERIES III., Case 19.—Mrs. R. W. K., aged thirty-eight years, came March 5, 1894 (a case in which about two years previously I had given the opinion that I did not think I could improve her hearing). Both membranes had large perforations from scarlatinous otitis suppurative thirty-seven years ago; had for years noticed a gradual diminution of hearing. Hearing for voice very poor, watch not heard, tinnitus deep in character. Treatments were given every other day. April 24th she heard a thunder-clap, a sound which she had not heard before for fifteen years. May 9th she heard a dynamite explosion (quarrying) some four miles off. May 17th. Watch: right ear, eight inches; left ear, fifteen inches+; voice-hearing fair. Her friends have been so astonished at her markedly improved hearing that I have heard of this case in many quarters.

SERIES IV., Case 25.—Two cases of deaf-mutes very much improved. Miss E. G. came January 28, 1894, with history that when eighteen months old she had scarlet fever; that the ears were painful; that lymphatic glands below ears enlarged and opened; that from this time on she heard apparently nothing, but felt violent jars only; that she has endeavored to

utter sounds which seemed to resemble words; that two unfavorable opinions had been given by specialists on the case. By careful treating I arrived at the conclusion that the auditory nerve endings were, at least to some extent, sensitive; that however, it took a powerful sensation to excite them, and that it took a long time for a sound message to be perceived by them. For a month I used the usual treatment for such cases. On February 28th I commenced the use of phono-massage and mixed massage, and later pneumo-massage was applied twice a week, and now she can readily hear my watch tick, hears the friction cards easily, and the tuning fork annoys her by reason of the intensity of sound. Voice-hearing is not good, but she hears a loud voice if words are slowly uttered (sluggishness of perception of auditory nerve), and she has increased her vocabulary from *nil* to several hundred words, and is now able to converse with other children quite readily, as well as with her parents.

Series V., Case 27.—Miss S. B. came March 15th with history of catarrhal middle ear disease of twelve years standing; tinnitus has been constant for ten years; she has been treated for periods of a year or more by two Philadelphia specialists, but with no material improvement. The membranes are very much thickened and the lower portion is adherent to the promontory. Voice-hearing very poor, watch not heard, friction cards heard occasionally only. After treatments the only change has been a lessening in the frequency of the sounds; they are no longer constant. The case is one of atrophic catarrh.

I will take the liberty of calling attention to another case which illustrates that the improved hearing is not a temporary affair lasting for a few minutes or hours, but that the change for the better is a permanent one. I refer to Case 24.

Case 24.—Miss G. R. B., aged twenty-two years, came May 3d, with a history of catarrhal disease of middle ears of five year's standing. She had upon three occasions placed herself under the care of specialists in New York and Philadelphia without satisfactory results. The voice-hearing was poor, except when aided by lip reading. Watch: right ear, half inch; left ear, hard contact. Both membranes were retracted, lustreless, and thickened; very little movement of the membranes could be observed with Siegle speculum. After usual local treatment there was no discernible effect upon the ears; after the use of pneumo-massage for thirty minutes there was a slight increase in hearing, watch being heard—right ear, three inches; left ear, two inches. Two days later, on testing, I found her watch-hearing to be: right ear, two inches; left ear, one inch. After pneumo-treatment, this rose to: right ear, four inches; left ear, three and a half inches. Two days later on testing her, found hearing to be three and a half inches right ear, three and three-quarters inches left ear. After the treatment the hearing rose to: right ear, five inches; left ear, four inches. Two weeks later, May 14, she heard on arrival in Philadelphia, in right ear, three inches +; left ear, two and a half inches +. After treatment, right ear, four and a half inches; left ear, four inches.

It is evident, from what has been said, that massage is a method which will prove of value in the treatment of diseases of the ears, that it will in many cases obviate the necessity of severe operations, and give better results. Unlike these operations, the parts are left intact, so that should massage fail there is still an opportunity for further measures.

It may be applied by any one of four methods which, for convenience, although not strictly accurate, may be termed: 1. Pneumo-massage; 2. Pressure-massage; 3. Phono-massage; and 4. Mixed massage. The method to be employed corresponds to the case in hand; the caution to be observed is, in cases where the internal ear is affected, not to use too violent pneumo-massage, nor too shrill phono-massage, but to apply it most carefully, as otherwise there is danger of labyrinthine hemorrhage.

The time the massage is to be employed varies greatly with the variety employed, and the nature of the case in hand. Pneumo-massage can be used from two minutes in acute cases, to as much as an hour in chronic cases; and from about one minute when the shrill phono-massage is used, to fifteen minutes when the sounds are deep bass tones or are of small volume.

Of course, constitutional and other local treatments are as necessary when this method is employed as without it, although you will observe from my cases here quoted, that cases which had been treated and

thoroughly treated, and yet failed to improve, improved steadily when the massage treatment was adopted. In other cases where the regular ear treatment occasioned no change, the patient was transferred to the massage treatment, and improved markedly in a few treatments.

The following conclusions are a natural inference from the work herein portrayed.

1. Poor hearing, when unconnected with closure of the meatus or disease of the nerve, is usually the result of some want of mobility in the sound-conducting apparatus.

2. This want of mobility can almost always be overcome by the use of massage, especially pneumo-massage applied directly to the membrana tympani or ossicles.

3. That the pneumo-massage in ordinary cases is the most serviceable, phono-massage being especially indicated where there is a necessity of exciting the atony of the auditory nerves caused by disuse.

4. That as the mobility of these parts increases, the hearing is restored and the tinnitus disappears.

5. That the results are most favorable in cases of hypertrophic catarrh, and in cases with retracted and perforated membranes following suppuration; less favorable in the proliferous variety of catarrh; and unfavorable in the atrophic variety and in cases of involvement of the auditory nerve-ending.

6. That the treatment will in great part supplant the removal of the ossicles and similar operations, which operations should never be entered upon for the restoration of hearing or the removal of tinnitus until massage methods have been given a thorough trial.

TRANSLATIONS.

THERAPEUTICAL SUGGESTIONS FROM FOREIGN JOURNALS.*

SELENIUM AS A REMEDY LOCALLY.

Dr. Ch. Féré and Demontporcelet (*Wiener Medizinische Presse*, No. 23, 1894) have found selenium to be much more poisonous than sulphur to which it is chemically related. It must first be carefully experimented with before it can be employed internally. In certain skin diseases it will be found to yield much better results than sulphur under the same circumstances. It is a red amorphous powder and is employed under the form of precipitated selenium. They advise the following formula:

℞ Amorph. precip. selenium..... 2 | 0 (grs. xxx)
Pure vaseline.....30 | 0 (℥j)
For external use.

IODOFORM IN FIBRINOUS RHINITIS.

Dr. M. Vladár (*Pester Med.-Chirurgische Presse*, No. 16, 1894), in a case of fibrinous rhinitis where every means employed seemed to be without effect, insufflated iodoform well into the nostrils after previous irrigation, allowing the patient to respire deeply in order that he might draw it well in, and he was surprised with the results obtained. That night the patient slept for four hours and his nose did not become dry, the tense feeling diminished and the difficult swallowing decreased. The following morning all exudation had disappeared and only a sharply outlined and a but slightly bleeding raw surface remained, which soon healed under treatment by iodoform. No new exudates formed. Since then he has treated five cases with this remedy exclusively and concludes that iodoform is a specific in this disease. This method is to be continued as long as there is any sign of new membranes forming. As the results are rapid, dermatol or the subnitrate of bismuth may be employed to assist granulation. Sometimes one must have recourse to cocaine in order to diminish the sensation of tension and the irritation. No disagreeable effects from its use were observed.

* In charge of the Translator, F. H. Pritchard, A. M., M. D.

IODIDE OF RUBIDIUM.

Prof. Neisser, (*Therapeutische Monatshefte*, No. 5, 1894) claims that this iodide is better tolerated by the stomach, the circulatory and the general system, than the iodide of potash. Its taste is more pleasant and milder. Prof. Schoeler finds it of advantage in elderly people, with diseases of the circulatory system. In several cases where the potash salt was badly borne, this preparation, if carefully used, was tolerated. Prof. Bunge has a favorable opinion of the remedy. The symptoms of iodism do not appear as soon nor as prominently, as with the potassic salt. It caused no gastric disturbances. Employed locally, by instillation, as a 5 per cent. solution in eye diseases, it acted well. Prof. V. Mering states that the iodide of rubidium is better borne and furnishes the same results as the iodide of potash, as it does not disturb the stomach. He thinks it especially indicated in debilitated individuals, with weakened heart's action. Dr. Braunschweig, Dr. Leistikow and Prof. Wolff, also claim for this salt a better action than from the potash compound. It forms white, ordorless crystals which are soluble in water. The dose is the same as that of the potash preparation:

℞ Iodide Rubidium,..... 5 | 0 (℥j grs.xv.)
Destilled Water.....200 | 0 (℥vj. ℥ij.)
A tablespoonful three times a day.

ICHTHYOL IN GONORRHOEA.

Dr. Villetti (*Journal De Medicine De Paris* No. 21, 1894) from a numerous series of observations concludes that ichthyol is of service in the treatment of gonorrhœa on account of its being antiphlogistic, analgesic and germicide. He also praises it in cystitis. In gonorrhœa he employs injections of a 5 per cent. solution, while in cystitis a weaker one (1 per cent.) is used.

Diphtheria.

℞ Carbolic acid..... gtts. viij
Liq. sulph. iron..... ℥ij to ℥iij
Glycerine..... ℥i
M. Sig.—Apply to fauces with camel's hair brush two or three times daily.

CORRESPONDENCE.

NOTE ON HYDROPHOBIA.

EDITOR OF MEDICAL AND SURGICAL REPORTER:

SIR:—Apropos of Dr. Hiram Corson's recent articles in the REPORTER upon the subject Hydrophobia, I herewith direct attention to a method of treatment said to have been highly esteemed during the first quarter of the present century. Placed side by side with modern therapeutic methods, Pasteurism for instance, it savors of the ridiculous, nevertheless it was considered of sufficient value to merit recognition from the Legislature convened at Albany, February 28, 1806. The following as a verbitum copy of an article taken from in Albany, paper bearing date March 24, 1806.

State of New York, Comptroller's office.

Pursuant to the directions of an act entitled, "An act for granting a compensation to Jno. M. Crous, for discovering and publishing a cure for the hydrophobia, or canine madness, passed the 28th of February, 1806, I do hereby certify, that the said John M. Crous hath this day deposited in this office a certain writing, purporting to be the remedy used by him with perfect success, for more than twenty years past for the cure of the hydrophobia or canine madness, which writing is in the words and figures following to wit:

CURE FOR THE BITE OF A MAD DOG.

"The following is an account and prescription of the remedy and cure for the hydrophobia or canine madness, made by John M. Crous, in conformity to an Act of the Legislature of the State of New York, passed at their present session, viz:

1st. Take one ounce of the jaw bone of a dog, burned and pulverized, or pounded to fine dust.

2dly. Take the false tongue of a newly foaled colt; let that also be dried and pulverized—and

3rdly. Take one scruple of the verdigrise, which is raised on the surface of old copper by laying in moist earth; the coppers of George I or II are the purest and best. Mix these ingredients together and if the patient be an adult or full grown, take one common teaspoonful a day, and so in proportion to a child according to its age. In one-hour after, take the filings of the one-half of a copper of the above kind, in a small quantity of water.

The next morning fasting (or before eating) repeat the same as before. This, if complied with after the biting of the dog and before symptoms of madness, will effectually prevent any appearance of the disorder; but if after the symptoms shall appear, a physician must immediately be applied to, to administer the following, viz: Three drachms of verdigrise, of the kind before mentioned, mixed with half an ounce of calomel, to be taken at one dose. This quantity the physician need not fear to administer, as the reaction of the venom then diffused through the whole system of the patient, neutralizes considerably the powerful quality of the medicine—and

Secondly, if in four hours thereafter the patient is not completely relieved, administer four grains of pure opium, or one hundred and twenty drops of liquid laudanum.

N. B.—The patient must be careful to avoid the use of milk for several days after taking any of the aforegoing medicine.

JOHN M. CROUS.

Albany *ss.*

John M. Crous being duly sworn deposeth, that the above account and prescription for the remedy and cure of the hydrophobia or canine madness, is a just and true account and prescription, and the only one used and practiced by himself for more than twenty years past, and which has never failed of perfect success in any instance of the vast number of unfortunate beings who have been bitten by the mad dog, and who have applied to him, the deponent, for relief.

JOHN M. CROUS.

Sworn the 24th day of March,
1806, before me, James Kent,
Chief Justice, &c.

While the above has the flavor of mediaeval superstition, one cannot but wish that the average legislator of to-day, was as ready to recognize and further the rapid advance made in scientific medicine, as were our forefathers the crude attempts of a century ago.

Respectfully,

WILLIAM H. SHIPPS.

EDITORIAL.

BERI BERI.

The occurrence of beriberi or endemic poly-neuritis at the port of Philadelphia last winter, proves that even so rare adisease as this occasionally falls under our observation, and, with the increased and closer communications between the United States and Japan, China and India, together with the great reduction in time that has been brought about by the increase of speed in the steamships, makes it probable that, in the future, a larger number of cases may be imported. It is more than probable that, under the name of beriberi, a number of conditions are included, each of which is characterized by the symptom of poly-neuritis. Many cases develop from the exclusive use of rice, and it is not improbable that, under these circumstances, the rice is spoiled; in the spoiling a fungus has developed which, when taken, produces the symptoms of this disease. Pellagra, a disease not uncommon in certain portions of Italy, and caused by spoiled corn, produces very marked neuritic symptoms. Reasoning by analogy, one may expect that a similar change in rice would be able to produce analogous changes in the nervous system. It is very certain that a number of the cases presenting the clinical picture of endemic poly-neuritis are produced by decomposing fish, cases of which have been reported by authors in this and other countries. In at least three of the cases that occurred at the Lazaretto this causation was unmistakable, the men having existed chiefly upon fish, much of which was decomposed, for the greater part of the voyage, which lasted 80 days. Muscarin and other chemical poisons are able to produce well-marked inflammatory changes in the nervous system, and one may readily understand how decomposing fish could produce multiple neuritis.

As Scheube has so well stated in his aecent admirable monograph on this disrese, beriberi is not contagious, at least in the sense that measles is communicated from the sick to the well, but is more like malaria in its transportability. Numerous bacteriological studies of beriberi have been made during the past 15 years, but the

results are contradictory and unsatisfactory, so that, in our present state of knowledge, we are compelled to admit that no definite organism has been proven to be the cause of this disease.

The diagnosis is easy when the possibility of the occurrence of this disease is taken into consideration, and where it does not occur in the so-called rudimentary forms, where the symptoms are all poorly developed. The well-known atrophic and dropsical forms are easily recognized.

The mortality from this disease is low, and varies in different epidemics from 5 to 15 per cent.

The treatment is purely symptomatic in view of our ignorance as to the essential cause of beriberi. The treatment of the neuritis is the same as for that from other causes; the cardiac phenomena and dilatation is best overcome by rest in bed and the use of full doses of digitalis, to which may be added strychnia. Good hygienic and climatic surroundings are particularly beneficial, and should be secured to the patient when possible.

SUPERSTITION IN NEW YORK.

In the *New York World*, June 20th, we find the following advertisement:

"CAUL FOR SALE, reasonable. Address ———, box ——, World, uptown."

It is more than two centuries since Sir Thomas Browne wrote—"Great conceits are raised of the involution or membranous covering, commonly called the silly-how, that sometimes is found about the heads of children upon their birth, and is therefore preserved with great care, not only as medical in diseases, but effectual in success, concerning the infant and others, which is surely no more than a continued superstition. For hereof we read in the Life of Antoninus, delivered by Spartianus, that children are born sometimes with this natural cap; which midwives were wont to sell to credulous lawyers, who had an opinion it advantaged their promotion." In a foot note the editor states that "even till recently the opinion has been held, that a child's caul would preserve a person from drowning. In the *Times* of May 6, 1814, were three advertisements of fine cauls to be sold at considerable prices specified."

That this superstition still lives in New York City is certainly remarkable. We wonder if the purchasers of cauls are lawyers who desire to be eloquent, or persons exposed to the perils of ocean travel. It will cost less to buy a caul than to go to Ireland and kiss the Blarney Stone, an osculation which few but fools would attempt, when the difficulty and danger of the effort appear; it would cost less too, than the ordinary life preserver, and might dispense with life boats. How profitable the sale of cauls might be made by maternities. Here is a branch of infant industry which needs no protection, and who knows how vastly it may extend, if the advertisement we have quoted can be taken as a sign of the times, or even as one of the ways of the world!

ABSTRACTS.

DYSMENORRHŒA.

Dr. Howard Kelly, of Baltimore, maintains with cogent reasons and no uncertain voice the proposition that dysmenorrhœa is not a disease *per se* and of striking importance, that it *is* a symptom only of an inflammatory product or new growth in the pelvis and *outside* the uterus. It is necessarily implied in his argument, though Dr. Kelly does not state it explicitly, that the causes of dysmenorrhœa operate by an interference with the normal circulation of blood in the pelvic vessels. For only in this way could extra-uterine inflammation and small fibromata cause pain with the menstrual flux. Another notable fact is that Dr. Kelly makes no mention of the still popular myth "obstructive dysmenorrhœa," which is defined by its advocates as a painful flux induced *directly* by flexions of the uterus which, by narrowing the canal just above the cervical junction, interfere with the free escape of the menstrual blood. Nor does he give any intra-uterine conditions as *causes* of this symptom; even the reigning fad "endometritis" is not referred to as a causal factor.

We have always believed that both dysmenorrhœa and endometritis were symptoms of some form of extra-uterine inflammation, whether in the neighborhood of the uterus or other pelvic organ, which by its presence interferes with the normal function of the afferent and efferent vessels supplying the organ involved. The periodic character of the pain is easily appreciated if we consider that at the time of menstruation the pelvic blood vessels are many times increased in size and an inflammatory swelling of any character in the pelvis, which during the intermenstrual period might interfere little with the pelvic circulation, would in the dilated state of these vessels prove a most serious obstruction to the necessary flux. Especially is this true of inflammatory thickening of the connective tissue which furnishes support to the blood-vessels in the anterior and broad ligaments of the uterus. Between the reduplication of peritoneum which forms these ligaments pass many of the largest vessels in the pelvis, supported and surrounded, as are blood-vessels in all parts of the body, by trabeculæ of connective tissue. As this tissue in these ligaments is necessarily of small amount, a slight increase of its cells, as in congestion or inflammation, must prove a serious obstruction to the function of its enfolded vessels when these are dilated. The effect of new growths as a factor in obstruction will to a great extent depend upon their situation.

The *raison d'etre* of our belief that this is the rational explanation of dysmenorrhœa is the same cogent one adduced by Dr. Kelly. We have never seen a case of this symptom in which the evidences of extra-uterine inflammation or the presence of a new growth was not clearly marked, and we have never failed absolutely to cure the dysmenorrhœa when we have applied our treatment directly to the offending part—whether peritoneal or cellular inflammation, diseased tube or ovary, new growths or inflammatory adhesions. As to so-called "obstructive dysmenorrhœa," it fails to appeal to our reason that a flexed uterus through whose canal a large-sized sound can be immediately and easily passed (as may frequently be done in these cases) can be the direct cause, *per se*, of obstruction to the outflow of blood.

We believe, further, that when the profession at large comes to recognize flexures of all kinds occuring in a normally developed uterus as a symptom merely which indicates the presence of an obstruction, somewhere in the pelvis, to the normal flow of blood to and from the uterus, many a puzzling case will receive its happy solution.—*New York Journal of Gynecology and Obstetrics.*

IS MEMBRANEOUS CROUP DIPHTHERIA?

Notwithstanding the investigations which this question has provoked during the last decade, there is still quite a diversity of opinion concerning the identity of these two affections, and considerable time must elapse ere a positive answer may be given to the query which forms the title of this paper.

In the past few years the bacteriologist and microscopist have stepped prominently to the foreground, and to their indefatigable labors and their valuable investigations and experimentation are we indebted for the marvelously rapid strides forward which medical science has taken. Our ideas of the etiology of disease have radically changed, and in consequence of our increased knowledge in this direction our methods of preventing and treating disease have become much more effective.

Through these bacteriologic investigations the discussion has arisen concerning the identity of membranous croup and diphtheria, and although the investigations in this matter may be said to be yet in their infancy, they have proceeded sufficiently far to convince many of the workers that the two diseases are one and the same, viewed from an etiologic standpoint.

As I stated, however, these investigations have but recently been commenced, and in this controversy I fear that we have depended too largely upon the statements of our friends, the bacteriologists, and paid insufficient attention to those men who see disease at the bedside as well as in the laboratory. The opinions of intelligent men who are daily in contact with the clinical manifestations of disease are certainly of great importance.

In treating this subject, I shall commence with this consideration of the etiology of diphtheria, as it is generally accepted at the present time. Without burdening you with a discussion of the predisposing causes, with which you are all familiar, I will proceed at once to the exciting cause which is contagion.

The disease is now known as the Klebs-Loffler bacillus, which was first described by Klebs and afterwards more extensively studied by Loffler. The production of the false membrane is the primary or local result, while the secondary or constitutional symptoms are due to the absorption of the poison generated by the Klebs-Loffler bacillus.

In the examination of the diphtheritic membrane, however, it has not uncommonly occurred that the characteristic bacillus was absent, and only streptococci, staphylococci, and at times other cocci were present.

The streptococcus, staphylococcus, etc., were also found in those cases, wherein the Klebs-Loffler bacillus existed, and in these cases the attacks were almost invariably more severe than when these cocci were absent. This fact has been accounted for by the supposition that these cocci penetrated parts that the Kelbs-Loffler bacillus did not reach, it being confined entirely to the membrane.

Baginsky, in a paper recently read before the Berlin Medical Society gave the following statistics: Out of 154 cases of diphtheria he obtained cultures of the Kelbs-Loffler bacillus in 118 instances. In the remaining thirty-six cases the streptococcus and staphylococcus alone were found; of this latter class, thirty-two of the cases terminated in complete recovery, unhindered by any complications.

From these observations, Baginsky is strongly inclined to the opinion that there occur two separate and distinct forms of diphtheria; a true diphtheria having for its cause the Klebs-Loffler bacillus; and a pseudo-diphtheria, in which streptococci and other cocci are the etiologic factors. Dr. T. M. Prudden, of New York, publishes an account of his investigations, which comprises twenty-four cases. A vast majority of these cases occurred as a complication or sequel to scarlatina, and in none was he able to demonstrate the presence of the Klebs-Loffler bacillus. Martin publishes an account of the examination of 200 cases, in 79 of which the characteristic bacillus was absent, and in this latter class the mortality was very markedly lower than in those cases characterized by the presence of this bacillus.

Dr. Wm. H. Park, of New York, states that in 127 cases in which the Klebs-Loffler bacillus was found to be present, the mortality was 34.2 per cent. while in 79 cases in which it was absent,

the mortality was but 4.3 per cent. Park also says:*

"The inflammation caused by the streptococci and to a less extent by other cocci, differ greatly. They may be conveniently divided into :

1. Pseudo-membranous angina.
2. Pseudo-membranous laryngitis.
3. Croupous tonsillitis.
4. Follicular tonsillitis.
5. Acute pharyngitis and tonsillitis without exudate.
6. Cases similar to all the preceding, but complicating infectious diseases."

From the above facts I would glean the following points, the correctness of which is accepted by many.

1. That those cases which we have heretofore diagnosed as diphtheria are divided into two classes, one of which constitutes true diphtheria, the etiologic factor of which is the Klebs-Löffler bacillus, while the other class consists of cases of exudative tonsillitis or pharyngitis, caused by the presence of streptococci, staphylococci, etc.

2. That true diphtheria is a disease attended with a very high death rate, the severity of the affection being caused by the absorption of a toxalbumin, which is generated by the Klebs-Löffler bacillus, and which produces septicemia, paralysis, albuminuria, ganglionic engorgements, etc.

3. That uncomplicated exudative pharyngitis or tonsillitis (so-called pseudo-diphtheria) is followed in a vast majority of cases by complete recovery.

4. That only the true diphtheria is contagious.

I will next briefly consider the etiology of that affection known as membranous croup. The exciting causes of this affection were until recently supposed to be exposure to cold and moisture, and the infectious diseases, contagion having no etiologic importance.

It is now claimed by many writers of authority that the disease is produced by the Klebs-Loffler bacillus, and is in consequence diphtheria.

Frankel records four cases of idiopathic membranous laryngitis, in none of which was there any membrane found in the fauces either before or after death; but in all four of these cases pure cultures of the Klebs-Löffler bacillus were obtained; and he concludes as a result of his investigations that idiopathic membranous laryngitis and diphtheria are etiologically identical.

Other investigators whose opinions are also worthy of respect and consideration have arrived at practically the same conclusion.

It should be remembered, however, that the examinations of the membrane of croup have been comparatively few, and, although we have proof positive that many cases of croup are in reality true diphtheria, the investigations have not as yet proceeded sufficiently far to admit of the opinion that all cases are produced by the characteristic diphtheria bacillus, or to make such opinions of any great value.

If, however, this is the case, then membranous croup must of necessity be a highly contagious disease, and right here is the stumbling block in the pathway of the advocates of this theory.

In studying the literature of the subject I have been unable to obtain any tangible evidence of the contagiousness of this affection. On the contrary, I find abundant testimony to the effect that the possibility of communication from one to another does not exist.

Osler, in his recent work on the "Practice of Medicine," states that he has twice observed cases of membranous croup in the Infants' Home in Baltimore were the conditions favorable to the spread of the disease existed, yet no other cases occurred. Other authorities agree with this opinion.

It has been my own misfortune to have had in my charge, at various times, four cases which I believed to be idiopathic membranous laryngitis, the last one occurring about one year ago.

At the time of my attendance upon these cases I gave little or no thought to the possibility of contagion, especially as there was no exudate visible on the fauces. Consequently no precautionary measures whatsoever were taken. The patients were not isolated, other children being allowed the freedom of the sick chamber.

In each of these cases there were other children in the family, of an age rendering them susceptible to contagion. In one other family there were four other children under the age of twelve years. Neighbor children were also allowed by

*Annual of the Universal Medical Sciences, 1893, Vol. 1.

the family in and out of the room and were frequently in close contact to patient. This occurred in two cases. In not one of these four families did there develop a case of diphtheria, neither was there an appearance of the disease in any of these neighborhoods. It seems to me that these cases would have formed excellent nuclei for an epidemic had the trouble been true diphtheria.

Such experiences have occurred, I have no doubt, to nearly every one within the sound of my voice. What would be the result if we were to handle a case of diphtheria in this fashion? We would undoubtedly have a nest of diphtheria to pay for our negligence. It may be said in answer to this, that in the majority of cases we have but one patient in the family, the disease not extending to other members. This is true, but the precaution every physician takes to prevent the spread of the disease is the reason for it. How many physicians five years ago took these same precautionary measures in membranous croup?

In further support of the view that many cases of membranous laryngitis are due to causes other than diphtheria, permit me to briefly present some statistical facts.** From 1775 to 1850, diphtheria was almost or quite unknown in this country and in Great Britain, but many cases of non-contagious membranous laryngitis occurred during this period.

In Philadelphia from 1846 to 1849 the annual mortality from croup was from 111 to 312. Do deaths from diphtheria are recorded during this period. From 1860 to 1879 the annual mortality from croup ranged from 185 to 455, while from diphtheiria it was from 110 to 708.

Previous to 1859, when diphtheria made its appearance in Philadelphia, there had occurred altogether 3,078 deaths from croup, during which period, no diphtheria was encountered so far as is known.

In New York City previous to 1858, but three deaths from diphtheria occurred during the present century, while croup had been more or less prevalent.

From 1858 to 1875 the annual death rate from croup ranged from 338 to 758, while that from diphtheria was from 5 to 2, 329. Dr. Lewis Smith, in this connection makes the following observation: "It is evident that most of the cases of croup occurring in New York prior to 1858 were due to other causes than diphtheria. It seems hardly probable that so many cases occurring in the hands of hundreds of skilled practitioners should have presented none of those symptoms which we now recognize as characteristic of diphtheria, especially septicemia. It is probably an acute, non-contagious, non-infectious inflammation of the larynx, local in character. But there is also a true diphtheria (laryngeal), and this is the more common form at the present time."

The two diseases present some differences in their clinical aspects. In diphtheria the initial symptoms are slight chilliness, fever, aching in back and limbs, etc. In croup the first symptoms are slight hoarseness accompanied by a rough cough, while there is little or no elevation of temperature.

In diphtheria, the temperature gradually rises, generally reaching 108 or higher, while in croup the temperature is ordinarily much lower than this and not infrequently it remains normal. In diphtheria the first indication of local trouble is slight redness of the fauces and more or less difficulty in deglutition. In croup we have in addition to the cough and hoarseness, which gradually increase in severity, dyspnea, which gradually becomes more and more intense.

In diphtheria, the exudate in the vast majority of cases makes its initial appearance upon the tonsils, later extending to the pillars of the faucus, the uvula and even to the posterior pharyngeal wall; later, in some cases extending into the posterior nares or downward into the larynx, trachea and bronchi. In croup, the membrane invariably first appears in the larynx, from this point extending upward or downward or both. In diphtheria, we generally have a characteristic grandular swelling, which is absent in croup. Constitutional symptoms are prominent in the former disease and absent in the latter. In croup, all the symptoms are rapidly increased in severity, the dyspnea becoming intense. Cyanosis soon appears, and death generally closes the scene.

Should the diphtheria be laryngeal in character, there would not be such a wide divergence in the smyptoms. Still the fever would be higher than in croup, glandular swelling would occur and the constitutional symptoms be marked.

** Reference Hand-book of Medical Sciences.

Two of the cases of croup in my own practice, to which I referred, had absolutely no rise of temperature at any time, and in all four of the cases no glandular swelling existed and no symptoms characteristic of diphtheria were present.

In the earlier portion of this paper we have seen that there occurs a true diphtheria, highly contagious and very fatal; and a so-called pseudo diphtheria not contagious and much less fatal than the former affection. We have seen that the etiology of these two diseases is very different.

Is it not possible, nay, even probable, that these same conditions prevail with reference to the laryngeal mucous membrane? I would answer the question affirmatively, and would further strengthen this opinion by studying the history of diphtheria and croup as they occurred in this country during the present century, and to a certain extent by the study of the clinical manifestations of the two affections.

The conclusions, then, which I have reached are as follows:

1. That there are two forms of membranous laryngitis; one a true diphtheria, produced by the Klebs-Loffler bacillus and the other non-contagious membranous laryngitis, produced, if you please, by streptococci, staphylococci, etc.; and that both of these types are very fatal.

2. That membranous croup as we have heretofore understood it, is a disease of much less frequency than was formerly supposed.

3. That it being impracticable to make a bacteriologic examination of the membrane in many cases, and as this is the only method by which we may be absolutely positive of our diagnosis, the same precautionary measures should be taken to prevent a possible spread of the disease as would be adopted in a case known to be diphtheria.

Those who believe that a non-contagious membranous croup does not exist will hardly be favorably impressed with the idea of carding the house, isolating the child, and causing any other children who may be members of the family, to remain from school several weeks, but in the light of our present knowledge upon the subject it is the only safe method to pursue, unless a careful microscopic examination by a competent bacteriologist has demonstrated the absence of the Klebs-Loffler bacillus.—*F. C. Woodburn in Jour. Am. Med. Ass'c.*

THE ABSORPTION OF IRON.

The importance of iron in the nutrition of the animal body has long been recognized, but there has been many and varied speculations as to the way in which the iron is utilized by the system. Obviously, the bulk of the iron actually absorbed eventually enters into the hæmoglobin of the red blood corpuscles, and that, no doubt, represents one of the chief functions of this element. Still, it is to be remembered that when iron enters into an organic compound it cannot always be detected by the ordinary reactions, and hence we have to admit the possibility of its wide-spread distribution through tissues and organs hitherto considered free from this element. Indeed, Macallum has shown by the use of micro-chemical methods that the most important of all elements in the life of every cell is an iron-containing compound; even the prozymogens, if not the zymogens themselves, found in the various secreting glands, contain some iron, so that it is quite possible that iron is essential for the life and well-being of every tissue cell.

To a person interested in nutrition, the question naturally arises how, and in what forms, is iron absorbed? Can the iron needed for the wants of the body be supplied by organic iron salts, or must it be introduced in the form of organic iron compounds? Further, assuming that the inorganic compounds are available for the needs of the organism, are they directly available or must they first be converted through synthetical processes into complex organic compounds before they can serve their full purpose as nutrients? These questions have been variously answered by different observers, so that at the present time our knowledge of this matter is in a somewhat uncertain condition.

In an article just published by Dr. Macallum, of the University of Toronto,* we

* On the Absorption of Iron in the Animal Body. *Journal of Physiology*, Vol. xvi., p. 268.

find recorded many interesting results bearing upon these questions; results well worthy of consideration, for they were obtained by carefully conducted feeding experiments followed by micro-chemical examination of the various tissues and organs. Experiments made with guinea-pigs, for example, show that when inorganic iron compounds are fed a certain amount of the iron is absorbed in the intestinal mucosa. Further, it was noted that the accumulation of iron in the mucosa, when the dosage was small, was limited to the sub-epithelial portions of the tips of the villi, the iron being deposited in leucocytes which in their disposition form a sort of cap for the extreme end of the lacteal vessel. That the iron in these leucocyte cells originates from the food was plainly apparent from the fact that the tips of the villi gave only a feeble reaction for iron when the animal was deprived of food for some days. In well-fed animals, on a normal diet, the iron reaction is most marked in that portion of the intestine closely adjacent to the pylorus; even ten inches away from the pyloric orifice the iron reaction may be entirely negative. When, however, inorganic iron compounds are fed, the area of absorption and the extent of the deposition of the iron are determined mainly by the nature and quantity of the compound given. Thus, when the amount of iron fed is large, the absorptive area may embrace the whole length of the small intestine, and the iron may be found not only in the underlying elements, where it seems to be specially transferred by the epithelial cells, but also in the epithelial cells themselves. This is explained by Dr. Macallum as follows: "The iron salt of the chyme, when the latter is thoroughly mixed with the biliary and pancreatic fluids, becomes wholly precipitated if the alkalinity of the two latter fluids is sufficiently great. The alkali present may be completely destroyed by a large quantity of iron salt in solution, and when this occurs the excess of the iron salt not precipitated and remaining in solution is absorbed. When the quantity in excess of that necessary to destroy the alkalinity is very great, all the villi of the intestine are in a position to absorb some of it. If, on the other hand, the dose is small, absorption in the upper end of the intestine is favored by the circumstance that the three fluids, chyme, bile and pancreatic juice, do not immediately and intimately mingle and, thefore, the iron is not at once precipitated, some of it being absorbed before that occurs. The quantity of acid in the chyme is a factor of some importance, and when the iron given is in the salt form and not as the oxide, the acidity of the chyme is not decreased, the acid of the salt displaced taking the place of the hydrochloric acid. When the oxide or the reduced metal is administered, their solution takes up a portion or all of the acid without contributing in turn to the acidity of the chyme, and, therefore, in the intestine the alkalinity of the bile and pancreatic juice goes further in the precipitation of the salts of iron in solution in the out-poured chyme. The larger the amount of free acid in the latter, the greater must be the quantity of iron absorbed."

When the amount of absorbed iron contained in the epithelial cell is small, that part of it in the lower end is dissolved in the protoplasm, but when the amount is large it appears to be precipitated in a granular form. The dissolved form of the iron compound is considered to be an albuminate, but the character of the granular form is less certain and it is equally difficult to determine the exact nature of the granular masses in the leucocytes below, although they are assumed to be of albuminative composition.

While the leucocytes plainly transfer the absorbed iron into the general circulation, it is probable that by far the greater portion of the absorbed iron, especially when the dosage is large, is carried from the villus by means of the blood-plasma and is then made use of as the requirements of the organism demand. In the words of Dr. Macallum, "It follows from the results of these experiments that inorganic and albuminate compounds of iron are absorbed, at least in the portions of the intestine near the pylorus, and in all parts of the small intestine where the iron compound is not precipitable on mixture with the bile and the pancreatic juice. Undoubtedly, also, sulphides in the bowel must remove from solution a quantity of iron in proportion to their abundance. In ordinary diet the extent of the mucosa which absorbs iron must be, in proportion to that which does not, remarkably small. It may possibly be that in the human subject when the iron is specially increased, the extent of the absorbing surface is increased, the more so when there is a di-

minution in the amount of pancreatic and biliary fluids, a condition possibly in anæmias. The view held by some that iron salts are not absorbed and that these exercise their effect by stimulating the mucosa to greater physiological activity, is opposed by the results of these experiments. If iron salts stimulate, it is because they penetrate the epithelium of the mucosa and in so doing are transferred to the underlying elements. In other words, they are absorbed. But the extent of the absorbing area is limited; so likewise must be the extent of the area supposedly stimulated and, therefore, the beneficial effects of the stimulation of the mucosa alone must be small. What, then, is the purpose served by the absorption of iron salts? Leaving out of consideration the possible answer that the iron of such combinations becomes assimilated; that is, is united in the animal cell with other constituents to form what the histologist calls chromatin, we may discuss some explanations of its effects. The experiments with the feeding of 'peptonate' and of albuminate of iron are, of course, too few to enable one to infer anything concerning the action of iron-holding proteids of this character, but all the experiments without exception indicate that the leucocytes have a special affinity for inorganic and albuminate compounds of iron, and it is not too much to infer that this affinity involves a stimulating or chemiotactic effect upon the leucocytes, and that iron salts exercise an effect on other cells corresponding to their function.

The number of leucocytes which are engaged at any one time in the absorption of iron is comparatively small, owing to the small extent of the intestinal mucosa bathed by a solution of an iron salt, and, therefore, the stimulating effect would appear to be small, but it must be remembered that, with the constant stream of iron-holding plasma and iron-holding leucocytes from the villi in the upper portion of the small intestine to the liver, spleen, etc., the other cells of the body, including leucocytes with little or no inorganic iron, are put in position to obtain some of that absorbed. There is also another way in which the question may be viewed. Inorganic compounds of iron, like those of calcium, potassium and sodium, have been since the dawn of animal life on the globe, constituents of its media and of its food, and it is possible that the animal cell has, in acquiring a tolerance for them, accommodated its functions to their presence and has established with them a physiological equilibrium which it may be impossible to maintain in the absence of such compounds. The view that the iron of inorganic combinations goes directly into combination with nuclein and albumin to form chromatins, is one that may in the future be proved correct, but whether it will happen so or not, it is not now, nor apparently will it be then, incompatible with the explanation of other possible functions of iron salts like those just referred to."

Dr. Macallum's researches also show that when iron is absorbed in excess of the needs of the body it is excreted through different channels in different animals, dependent, apparently, upon the degree of activity which the organs present in different animals. In man, the liver and kidneys are most active in the excretion of iron.

In studying the absorption of organic iron compounds, Dr. Macallum employed representatives of the so-called assimilated compounds of iron, such as the nuclein bodies, commonly known as the chromations. After some successful feeding experiments with chromatin isolated by artificial gastric digestion, recourse was had to unboiled egg-yolk, which, according to Miescher, contains 1 to 1.5 per cent. of nuclein (hæmatogen.) This chromatin appears to exist in the egg-yolk partly in the form of granules and partly as a membrane to the contained fat globules, the latter being quite small and "shading off into the small granules in such a way as to suggest that the latter are also fat globules of almost infinitesimal size surrounded by chromatin." This material evidently undergoes absorption in the intestine of the guinea-pig, and when fed for some days upon the above food the cytoplasm of the liver cells yields marked evidence of the presence of an organic iron compound belonging to the "chromatin" class and derived from the yolk fed. As to the way in which the chromatin is observed no definite statement can be made, but apparently the process is connected with the absorption of the fat with which the iron compound is closely associated in the yolk. Evidently, then, both simple iron salts and organic iron compounds can be absorbed and utilized by the animal organism. There are still, however, many questions to be answered relative to the way in which the iron serves its purpose in the economy.

VACCINATION AND REVACCINATION.

The periodic recurrence of more or less extensive epidemics of small-pox in various countries, even in those where vaccination is popularly believed to be very generally employed as a prophylactic, justifies also the periodic repetation in the medical and lay press of some of the very instructive and conclusive facts furnished by vaccination which it seems to us should set at rest forever any doubt or skepticism concerning the protective value of vaccination—were it not that these incredulities seem also to follow some law of periodicity as to their development and dissemination.

The experience we have recently had with small-pox in the United States, and the blatant illogical opposition to the practice of vaccination as not only possibly injurious but probably, also useless—which we occasionally hear voiced in diverse publications, (happily. usually foreign)—suggest to us the advantage of printing for the benefit of our readers an extract from a most carefully prepared comparative analysis of the results of vaccination and revaccination, by Dr. Goldschmidt of Strasburg, 1890.

It is, however, as a strong argument in favor of obligatory vaccination and *revaccination* that we would commend this abstract to the attention especially of those of our readers who interest themselves in shaping and aiding the enactment of legislation for the benefit of the public health.

The memoir in question contains (*Rev. de Méd.*, 1890, pp. 315-351) a large number of statistical documents upon the subject, among which are some most striking. From them it is shown that the city of Paris alone has more deaths from small-pox annually than has the whole German Empire.

Germany is the sole country where compulsory vaccination and *revaccination* has been practiced since 1875, a glance at the following table shows the striking result of this practice as a means of effectually exterminating small-pox.

ANNUAL AVERAGE OF DEATHS FROM SMALL-POX AMONG 100,000 INHABITANTS.

Prussia, 1860-69, before the compulsory law	33.84
Prussia, 1875-84, after vaccination and revaccination (compulsory)	2.23
Berlin, 1875-84, " "	1.68
Dresden, " " "	1.48
Breslau, " " "	1.61
Bavaria, " " "	1.11
Paris, 1875-84, vaccination voluntary.....	28.95
Paris, 1887, " "	17.20
Vienna, 1875-82, " "	84.37
Austria, 1875-84, " "	61.64
England, 1875-84, one vaccination obligatory	7.61
London, 1875-84, " "	25.50
London, 1887, " "	0.20

In 1886, in all Germany there died of small-pox 193 inhabitants, that is to say 0.4 per 100,000, a smaller number than that furnished by the city of Paris where there were during that year 218 deaths from the same disease; again, for the year 1887 the numbers were respectively 168 and 389. At Marseilles in 1886 there were 2,051 deaths from small-pox, a proportion of 545.3 per 100,000; it is true, however, that during the following year there were only 63 deaths; from the same disease or 16.7 per 100,000. But during this time there was only one death by the same cause at Berlin (0.07) and none at Dresden, Cologne, Breslau and Frankfort.

In the Prussian army 300,000 strong, from 1886-84 there was not a single death from small-pox, and there was only one in 1885 notwithstanding a total of 135 cases of the disease in ten years.

In the French army which counted an average of 460,000 souls, from 1876-85 there was an average of 627 cases and 54 deaths of small-pox per year, that is 12 deaths per 100,000 men. But in this period of ten years, with the extension of the practice of revaccinations, the number of deaths had been constantly decreasing, from 227 in 1879 to 6 (with 214 cases) in 1886; with the result that for the last two years the proportion was only one death per 100,000 men. It should not be surprising that, in the midst of the civil population of France which still suffers so much from small-pox, the French army furnished a larger number of cases and deaths of small-pox than does the German which is almost free from exposure to this contagion from the population which surrounds it. There exists in France no statistics which show the exact number of deaths from small-pox among the total population of the country.

Although the German law of April 8, 1874, makes vaccination and revaccination compulsory, as a matter of fact, 10.51 per cent. of the whole number of young child-

ren available for a primary vaccination and 3.5 per cent. of all the children of 12 years available for revaccination escape both of these protective operations. Variola may therefore still exert its malignant influence even in Germany upon a number of subjects—collectively large—upon whom vaccination has not conferred or has not restored immunity. Thus, in 1886 and 1887, infants from one to three years of age furnished nearly half the deaths from small-pox in Germany. In the latter country the practice of vaccination from arm to arm (with the so-called human virus) has greatly and constantly diminished since the compulsory law was enacted. For example, in 1879 the animal virus was used for only 2.50 per cent. of the children vaccinated; while in 1885 it was used in 33.10 per cent. of such operations. (Later statistics show a still more marked decrease in the use of human virus.) The objection raised in some quarters, especially, in some of the densely ignorant manufacturing districts of England, to the possibility through carelessness of the inoculation of loathsome constitutional diseases with the human virus certainly cannot have even any fancied weight when animal virus is used.

In Alsace-Lorraine the proportion of successful primary vaccinations has been 95 per cent.; for the *revaccinations*, it was 75.3 per cent. in 1885, 71.4 per cent. in 1886 and 79.6 per cent. in 1887. At Strasburg upwards of 8,000 children of 12 years of age *revaccinated* either from arm to arm with the human virus or directly with the animal virus, Dr. Goldschmidt obtained a proportion of success which varied from 79.80 to 75.59 per cent. This is large and is above that which has been usually obtained in France, but it is scarcely equal to that obtained by the revaccinations in Germany. It is true that the revaccinations take place at 12 years of age in Germany, while the figures in the French army (about 60 per cent.) concern young men from 20 to 21 years of whom doubtless a certain number have been already vaccinated before entering the service.

Dr. Weil, Cantonal physician in Hagnenan, cited by Goldschmidt, for 2,111 subjects revaccinated obtained a porportion of success which increased with the age of the subjects as indicated by the following table:—

Revaccinated.	*Percentage of success.*
From 6 to 7 years old	32.60
" 7 to 8 " "	64.00
" 8 to 9 " "	72.52
" 9 to 10 " "	79.63
" 10 to 11 " "	85.94
" 11 to 12 " "	88 64
Adults	90.00

The greater number of the 368 adults revaccinated had been vaccinated only in their early infancy and had certainly not been revaccinated previous to the operation in question.

These facts, and others like them which are accumulating constantly, prove the absolute necessity of revaccination, since they show that in 85 to 90 times in the 100 the immunity against small-pox conferred by the first vaccination has disappeared in twenty years; they also demonstrate in a most striking manner how certain a measure of public defense against the spread of small-pox is *conpulsory* and *revaccination. — Dietetic and Hygienic Gazette.*

Sugar as a Food.

Some recent results published by Dr. V. Harley, in the proceedings of the Royal Society of Great Britain, bearing on the influence of sugar as a food in the production of muscular work are full of interest. "The conclusions of his experiments, which were performed on himself with Mosso's eigograph are as follows: (1) Sugar when taken alone is a muscle food; 500 grams (7½ ounces) of sugar increased the amount of muscular work done on a fasting day, from 61 to 76 per cent. (2) The muscle energy-producing effect of sugar is so great that 200 grams (7 ounces) added to a small meal increased the total amount of work done from 6 to 30 per cent. (3) That when sugar was added to a large meal it increased the total amount of work done from 8 to 16 per cent. (4) That the work done during a period of eight hours can be increased from 22 to 36 per cent. by taking 250 grams (8¾ ounces) of sugar. (5) That when sugar is taken at 3.50 p. m., it not only obliterates the diurnal fall in the muscular power, which usually occurs at 5.30 p. m., but even causes an actual increase in the total amount of work done."—*Dietetic and Hygienic Gazette.*

CURRENT LITERATURE REVIEWED.

IN CHARGE OF ELLISTON J. MORRIS, M. D., AND SAMUEL M. WILSON, M. D.

THE VIRGINIA MEDICAL MONTHLY

For June contains a paper on

The Radical Cure of Aural Polypi.

by Dr. T. T. Churchman. The author states that after the ordinary methods have been tried faithfully without success, he advises the removal of the drum with one or more of the ossicles. In this way, by the removal of the polypus, drum, and one or more of the ossicles, the discharge will be cured and the recurrence of the polypus thereby prevented. In these cases where free drainage can be established, the author does not attempt to destroy the pedicle, for by the use of the proper antiseptic washes the exciting cause will be removed and the pedicle will atrophy and disappear.

Dr. Q. C. Smith contributes an article on

Placenta Prævia; How to Treat it.

If the cervix is relaxed so that the finger can be passed through it, the author advises that the finger be passed through the placenta and the waters evacuated, firm, steady, continued pressure being made over the fundus till other hæmostatic measures can be brought to bear. If the cervix is so small and rigid that the finger cannot pass through it then the author advises that the cervix be douched with what he terms "hop styptic water" (hot solution of alum) until the hemorrhage is partially or entirely staunched. The patient is then to be placed in the Sims' position, a speculum introduced and the hot styptic water injected through the cervix until all the hemorrhage ceases. The bladder is then emptied by means of a catheter and three to five grains of muriate of quinine and urea administered hypodermically and hot whiskey todies given till the patient is well under the narcotic and anæsthetic effect of the whiskey. If the cervix is still very rigid, a drachm of fluid extract of ipecac is to be given, as the author believes that large doses of ipecac are far more hæmostic and equalizing of nervous force than are small ones.

The cervix is now to be dilated using all the time the hot styptic water, and the placenta separated by means of a properly curved Simpson sound. The cervix is to be farther dilated by means of Barnes' rubber dilator. As soon as the cervix is sufficiently dilated and labor pains have come on with regularity the bags are removed, the placenta punctured with the finger and the presentation of the child discovered if possible. The child can then be delivered by the feet or by forceps as seems necessary.

Dr. J. Wesley Bovee discusses

The Conservative Treatment of Cancer of the Uterus.

The author urges the importance of a total hysterectomy so soon as the disease is discovered. He has little faith in the treatment by aniline preparations, at present in vogue in Europe, though it seems to retard the progress of the growth and render it less painful, and is therefore applicable to cases advanced beyond surgical aid. No remedy has yet been found that can compare at all favorably with surgical treatment, either as a radical operation for cure or for the removal of as much as possible of the diseased structures. We may reasonably hope for cure of cancer in the uterus if early extirpation be resorted to, but in the incurable condition our objects are to make the sufferer as comfortable as we can, and to prolong her life as much as possible.

Dr. M. W. O'Brien contributes an article on the

Treatment of Crushes of the Hands and Feet.

The author does not think that a hand crushed in the bumpers of a railroad car can be make surgically clean by any immediate washing or soaking in even the best hot antiseptic washes, so that a dry dressing can be put on as usually described and all go well. He has tried it many times, he states, and has had pus and fever and chill, so that the dressing had to come off and another course inaugurated.

The hot sublimate water dressing in crushes about the extremities is the ideal dressing, and has saved many hands and feet that, with any other line of treatment, would have come off at the point of selection.

In dressing a hand or foot in this way' first thoroughly wash and steam it with hot sublimate water (1 to 2,000); then, if any part is to be removed, trim it off and envelop the whole injured member in plenty of absorbent cotton, holding it in place by wrapping it with ordinary sewing cotton; put the part at rest comfortably on a sheet of rubber to carry the solution into a convenient receptacle, and assiduously soak it, at regular intervals, with 1 to 4000 sublimate water as hot as can be borne. By this means fever disappears, the circulation is coaxed into damaged tissues, granulations spring up, and the part is restored—this, too, without changing the line of local treatment except in degree.

There is one other fact in his experience in these injuries he thinks worthy of note. He has seen only one case of tetanus result out of a total of several hundred cases in the last ten years. This looks as though tetanus was exceedingly rare among injured railway men, though he does not see why it should be when all things are considered in connection with these cases.

Dr. George M. Kober continues his article entitled

A Study of the Soil in Relation to Health and Disease

Examination of the Soil.—A complete sanitary investigation should include the following points, viz:

(1) The configuration of the locality, height above the sea level, angle of declivity, facilities for natural drainage, water-sheds and courses, covering of soil by trees, brushwood, and grasses.

(2) Geological formation, dip and character of strata, especially in reference to their permeability.

(3) Examination into the size of the fragments or grains composing the soil is readily conducted by means of graduated sieves and a low power of the microscope.

(4) The porosity of the soil is usually determined by taking a liter of kiln-dried soil and ascertain how much water is taken up. The water must be added until air-bubbles cease to form. This is a simple, but not the most exact method.

(5) The *moisture* of the soil is determined by weighing a certain quantity; it is then exposed to a temperature of 220 until dry, and weighed again; the difference is water or some other volatile substance.

(6) The *capacity of the soil for holding water* is ascertained by thoroughly wetting a certain quantity previously weighed, drain off the water, and weigh again. This is not a precise method.

(7) *Measurement of the Ground-Water.*—The height of the water-level in wells is the best indication of the height of the ground-water. Pettenkoffer uses a rod for shallow wells and a cord for deep wells, to which are attached a number of little cups, which are let down into the well and drawn up again; the uppermost cup containing water, marks, of course, the height of the water, the length of this measure being known, the changing level of the well can be estimated to within one-half inch. Some precautions are necessary; for if a rope is used, it may stretch after prolonged use or during a hot wind, or shrink in wet weather, and thereby render the observations inaccurate, but not sufficiently so for practical purposes. It is best to use a rod in shallow wells, and the measurement should be made at a time when the supply has not been lowered by unusual consumption.

(8) *The ground air* is examined by sinking a shaft about sixteen feet deep, into which are placed lead pipes in 1½ feet, three feet, seven feet, nine feet, and fifteen feet lengths, and one-half inch in diameter. The soil is put back as nearly as possible into the original levels. The lead pipes are connected with an aspirator by means of rubber-tubing, and the aspirated air is examined for the determination of oxygen, carbonic acid, ammonia, hydrogen sulphide, and organic matter. The movements of the ground-air are determined by differential manometers.

(9) *Soil-pollution* is determined by a chemical analysis for the estimation of nitrogen and carbon. A simple way to ascertain the percentage of volatile matter is to take ten grammes of dried pulverized soil, incinerate at a red heat, recarbonate with carbonic acid solution or ammonia carbonate; heat again to expel excess of ammonia and weigh. The loss represents the amount of organic matter. The permanganate process is also applicable.

(10) The *micro-organisms* of the soil are best determined by using a borer invented by Frankel, and constructed on the principle of a butter-tester. This borer must be sterilized, and can be inserted to any desired depth. Upon withdrawal of the instrument, Frankel measures off, by means of a sterilized platinum spoon, a given quantity of the soil, and places it in a nutrient gelatine-culture tube, and shakes the mixture well. A small quantity of this is placed on glass plates under a damp glass air-chamber; and after the formation of the colonies, they are counted and isolated in the usual manner. The platinum measures hold about two grains of soil, as a larger amount would render the culture experiment very difficult and confusing because of the number of micro-organisms present.

(11) *The temperature of the soil* can be readily determined at any desired depth by placing a self-registering thermometer, properly protected, in a "drive well point joint."

Dr. Julius C. LeHardy in a paper entitled "Yellow Fever—Its Relations to Climate and to Hygienic Measures in the United States," after reviewing the various outbreaks of this disease, gives as his opinion that yellow fever acts, in every respect, like other epidemic diseases; its occurrence depends entirely upon the condition of the place. If cleaned and properly drained, the disease will not propagate whether in northern or southern latitudes, whatever may be the amount of rainfall, the heat of the sun, or the number of persons brought in with the disease.

The remaining papers in this issue are: "Auscultation of the Heart", by Dr. E. M. Macgruder; "Clinical Lecture on Hernia," by Dr. W. B. DeGarmo.

Under "Clinical Reports" is given a "Case of Dorso-Lumbar Spondylitis" illustrating the value of the jury mast, by Dr. Wm. J. Crittenden.

IN THE TEXAS SANITARIAN for May is a paper by Dr. F. C. Osborn entitled

Can Small-Pox be Aborted?

The paper is the history of a man vaccinated on the tenth day after exposure to small-pox and given one dose of calomel, and daily doses of hyposulphite of soda.

One week later the patient felt unwell, had headache, backache, nausea, temperature of 103°, and pulse of 92. A bath of warm water and soap was given, and a dose of calomel and ipecac.

In the evening the temperature was the same; but the face, neck, and chest were crimson, the lips swollen and sore, the tongue coated in the middle with white fur and intensely red at the edges, conjunctivæ injected, and the eyelids giving pain when moved. The bowels had opened.

The author thinks variola primarily a skin affection, and the constitutional disturbance secondary to it, and, expecting a variolous rash, he sponged his patient twice, once with a ten per cent. (sic) solution of bichloride, and allowed it to dry. Mouth, ears, nose

and eyes were washed with a solution of peroxide of hydrogen, and the great frothing following this showed its contact with pus or membranes full of bacteria, as otherwise it would be very scanty.

Seen the next morning the patient felt and looked well, had normal pulse and temperature and complained only of loss of sleep due to the prickling from the bichloride.

In this connection the author mentions curing a case of screw worms in the nose of a human being by injecting peroxide solution.

Other papers in this number are "The Nations Sin of Omission," by Dr. T. J. Bennett, an article on the necessity of a law restricting the practice of medicine by unqualified men. "The Conservation of Nervous Energy," by Prof. E. L. Blackshear. "Women and Sanitation," an editorial noting the increased interest shown in sanitation since the women of the country have taken steps to assist in perfecting it, and suggesting a radical change in the upholstery and general construction of sleeping cars.

IN THE JOURNAL OF CUTANEOUS AND GENITO-URINARY DISEASES

for June is an article by Dr. Eugene Fuller on

Chronic Seminal Vesiculitis.

The author states that, since the use of the electric endoscope is becoming more common, the so-called incurable urethral discharges are less frequently heard of, and yet we occasionally hear still of cases, which, after treatment for some time by well-known surgeons, were so obstinate that the patients gave up in despair, and finally, in some cases, seemed to cure themselves by venereal, or alcoholic excess, or a combination of these.

Success followed the treatment of many of these cases by stripping the seminal vesicles free from the pus which they usually contain, in this condition, by introducing the forefinger into the rectum. The method advocated differs essentially in object and procedure from the prostatic massage in use by some Russian authorities, and does not, as some suppose, require the possession of an unusually long forefinger. In fact the author thinks that a man possessed of even a short finger can by gentle persistence succeed in reaching and emptying the vesicles, if they are unhealthy. In cases where the patient is stout and muscular, the reinforcement of the surgeon's arm by his knee, as a rest, may be required at the first visit or two. When the vesiculæ are inflamed and the stripping is properly done, the pus and sometimes some blood, empties from the meatus. If, after this treatment has been used for a time, tenderness begins to increase, too much force has been used, and complete rest for a time is necessary. Typical cases are cited to show the symptoms to be expected and the results of treatment. The article will be continued later.

Dr. E. J. Stout reported a case of

Vanthoma Multiplex

The patient was a married seamstress of 50 years, who complained that one month after an attack of grippe, four years ago, she had a general jaundice. She has had rheumatism and, three years ago, syphilis.

The woman is five feet and one inch tall, is poorly nourished, and weighs one hundred and twenty-five pounds. She has headache, which has been much relieved by cutting the hair short. She feels drowsy during the day and falls asleep if not employed. Her general health is good, temperature normal, pulse sixty-four, appetite good, tongue badly coated, bowels regular, though the passages are diarrhœic and sometimes dark, sometimes clay colored. The patient is the color of a mulatto, and both conjunctivæ and mucous membranes of mouth are deeply jaundiced.

The rest of the body also is involved, but the legs and feet less than elsewhere.

Liver dullness, in the recumbent posture, begins in the sixth interspace, both anteriorly and posteriorly. In the normal position of the gall bladder is a very hard mass extending three quarters of an inch from the margins of the ribs.

There is no ascites. Examination of urine shows bile pigment, albumen, but no sugar; the specific gravity is (1010) and the reaction neutral. Nodular masses are felt on palpating the liver. The blood contains 4,640,000 red corpuscles per cu. cm. without increase of white conpuscles. Estimated hæmoglobin 60 per cent.

In February 1893, there appeared at the inner canthi of both eyes lesions of xanthoma palpebrarum, consisting of slightly elevated lemon yellow plates, about the size of a pea. The mucous membranes of the conjunctivæ and oval cavity, and the cornea are free from any similar growths. Along the natural furrows of the skin on the palmar surface of the hands, fingers, and the internal surface of the thumb are numerous similar lesions. The dorsal surface of the thumb and the knuckles of every finger are shedded with numerous similar lesions, varying in size from a millet seed to a large pea, and are velvety to touch.

On the dorsal surfaces the growths are lemon yellow, on the palms they vary from yellow to rose color. These growths do not coalesce and do not contain any liquid, but the patient complains of their itching and interference with work.

Below the right ear and along the angle of the jaw, and the inner border of the stennomostoid muscle similar growths vary in color from yellow to pink, and along the upper and interior borders of the scapulæ, along the arms near the axillæ, and along the extensor surfaces of the elbows these eruptions are arranged with considerable symmetry—resembling herpes to a great extent.

No history throwing any light on this disorder has been obtained from the patient, and no change, except that caused by excising a few lesions, has taken place while the patient has been under observation.

This disease, known under the following synonyms: Vanthelasma, vitiligoides, molloscum cholesterique, fibroma lipomatodes,

and defined by Virchow as a fibro-fatty neoplasm forming yellow plates or tubercles in the corium, has been regarded as an uncommon disorder, and the form most usually found is known as Xanthoma Palpebrarum and occurs as plates on the left upper eyelid, near the inner canthus.

When the disease takes an inflammatory form, fatty degeneration overtakes the leucocytes before they form tissue and they disappear as oil-drops, calcareous masses and cholesterine.

Hollopean thinks these benign neoplasms originate in embryonic generative fat cells, which persist and proliferate, and that the jaundice sometimes accompanying the trouble is due to the same cells in the bile ducts, and the glycosuria to their appearance in the pancreas. The etiology is still obscure however.

PERISCOPE.

IN CHARGE OF WM. E. PARKE, A.M., M. D.

MEDICINE.

Insomnia of Old Age.

Dr. J. W. Dale, in the *University —edical —agazine*, recommends very highly the use of morphia with a small amount of Dover's powder for the relief of the sleeplessness which is frequently one of the most serious complaints of the aged. The ordinary hypnotics, such as the bromides, chloral, and the numerous coal-tar derivatives, answer well for temporary purposes, but not where the demand is long continued. Dr. Dale gives at first from the 24th to the 12th of a grain of morphine, with two or three grains of the Dover's powder. This amount will need to be increased slightly as the patient becomes accustomed to it, but the doctor has found that even after a number of years, patients do not require an increase beyond a quarter of a grain of morphine and ten grains of the Dover's powder. Its use, he has found, is best limited to persons over 70 years of age, at which time of life its regular use is tolerated with impunity, and he has never found it to do any injury. The object in using the Dover's powder is to increase the bulk of the medicine, so that the patient will not be apt to increase the dose. Any particular increase would result in nausea from the presence of the ipecac. In addition to this, the small amount of ipecac present tends to maintain healthy action of the skin, and stimulate the stomach and the functional activity of the liver, as well as to diminish the tendency to constipation.

NEWS AND MISCELLANY.

DEER PARK

ON THE CREST OF THE ALLEGHENIES.

To those contemplating a trip to the mountains in search of health and pleasure, Deer Park on the crest of the Allegheny Mountains, 3,000 feet above the sea level, offers such varied attractions as a delightful atmosphere during both day and night, pure water, smooth, winding roads through the mountains and valleys, and the most picturesque scenery in the Allegheny range. The hotel is equipped with all adjuncts conducive to the entertainment, pleasure and comfort of its guests.

The surrounding grounds, as well as the hotel, are lighted with electricity. Six miles distant on the same mountain summit is Oakland, the twin resort of Deer Park, and equally as well eduipped for the entertainment and accommodations of its patrons. Both hotels are upon the main line of the Baltimore and Ohio Railroad, have the advantages of its splendid Vestibuled Limited Express trains between the East and West. Season excursion tickets, good for return passage until October 31st, will be placed on sale at greatly reduced rates at all principal ticket offices throughout the country. One way tickets reading from St Louis, Louisville, Cincinnati, Columbus, Chicago, and any point on the B. & O. system to Washington, Baltimore, Philadelphia or New York,or vice verse, are good to stop off at either Deer Park, Mountain Lake Park or Oakland, and the time limit will be extended by agents at either resort upon application, to cover the period of the holders visit.

The season at these popular resorts commences June 23d.

For full information as to hotel rates, rooms, etc., address George D. DeShields, Manager, Deer Park, or Oakland, Garrett County, Maryland.

SUMMER VACATION TOURS.

The Baltimore and Ohio R. R. Co. now has on sale at all its offices east of the Ohio River a full line of tourist excursion tickets to all the lake, mountain and seashore resorts in the Eastern and Northern States and in Canada. These tickets are valid for return journey until October 31st. Before deciding upon your summer outing it would be well to consult the B. & O. Book of "Routes and Rates for Summer Tours." All B. & O. Ticket Agents at principal points have them, and they will be sent post paid upon receipt of ten cents, by Chas. O. Scull, General Pass. Agent, B. & O. R. R., Balto., Md.

THE
MEDICAL AND SURGICAL
REPORTER.

No. 1950. PHILADELPHIA, JULY 14, 1894. Vol. LXXI—No. 28

ORIGINAL ARTICLES.

THE PROTECTIVE POWER OF VACCINATION.*

J. W. H. BAKER, M. D., Davenport, Iowa.

It is unnecessary to relate the history of the discovery of the protective influence of cow-pock virus against the contagion of small-pox made by Dr. Jenner. The discovery was made about a century ago, in 1797, since which time vaccination has been an art more or less practiced by the medical profession the world over. I therefore, limit myself to a few thoughts upon the written evidence of the *Protective Power of Vaccination.*

Prior to the discovery of vaccination for the prevention of small-pox, this disease was evidently the most destructive disease known. About 1520, it prevailed in Mexico, in which country it is reported to have destroyed three and a half millions of people. In 1707, it was introduced into Iceland where more than a fourth of the whole population fell victims to it. It reached Greenland in 1733, when it spread so fatally as almost to depopulate the country. Armies have been scourged by it and rendered helpless during their campaigns. Even now the announcement of its prevalence in town or village creates an unusual excitement or even a panic. What greater blessing could have been bestowed upon mankind than to remove this great fatality, and to relieve the people from the fear of destruction by such disease? The discovery of the power of vaccination has accomplished this, and at present it is no uncommon thing for people to assert that they have little fear of small-pox, or that they would rather have an attack of small-pox than any other prevalent epidemic disease, such as diphtheria, scarletina, or even measles.

What a change! And this all brought about by the discovery of and practice of vaccination.

Since small-pox is of such deadly character and is so much to be dreaded, it is not strange that at an early day—that is centuries ago—an effort to palliate its effect upon the people should have been made.

The first really practical effort to counteract or modify its effect or its general fatality was made by the introduction of the method of vaccination, or ingrafting persons with small-pox matter; either with the lymph from a genuine small-pox vesicle, or with the crust, or by an exposure of the person to a patient suffering with this disease.

This method of treatment came into notice more completely about 1715, and was introduced into England about 1721, and after a long trial was generally adopted by the medical profession of those times. We find that about 1746 the Small-Pox and Inoculative Hospital of London was founded for the express purpose of extending to the poor the benefits which had hitherto been almost exclusively confined to the rich.

In this method the natural disease was induced after the patient undergoes a preparatory treatment and through the after treatment a mild form of the disease was

* Read before the Iowa and Illinois Central District Medical Society, April 12, 1894.

produced, affording the person subsequent protection to the infection of small-pox. This method of treatment, with varied success and much opposition, prevailed more or less until the discovery of the protective influence of cow-pox by Dr. Jenner in 1797, since which time, now almost a century, vaccination has become the only method of protecting the people from the devastating effect of small-pox.

The adoption of Dr. Jenner's discovery was a matter of rapid progress among physicians and among the people, and the *Discoverer*, as early as 1802, was awarded $50,000 by the English Parliament; which amount was, in 1807, increased by the award of $100,000 more. This would in its first estimate now be considered a generous award, but when we consider its effect as a life-saving measure, it would be thought as only a "drop in the bucket."

Among the first publications of Dr. Jenner's discovery it was asserted that through this, small-pox was disarmed of its terror, and that "its complete extermination might reasonably be contemplated."

In the third publication of Dr. Jenner, dated 1800, he expresses his confidence that "the cow-pox is capable of extirpating small-pox from the earth."

The fourth publication, in 1801, concludes with the statement, "that it is now too manifest to admit of controversy that the annihilation of small-pox, the most dreadful scourge of the human species, must be the result of this practice."

These were strong assertions which, although never realized, in my opinion might and ought to have been.

This leads me to the matter of general interest as to the opinion of the protective power of vaccination at the present time, and some of the causes of its failure.

There is little doubt that the medical profession generally of the present day believe in the perfect protection of the person who is completely or perfectly vaccinated. I quote: "The fact is conceded on all hands that the true '*vaccine disease*,' which is in all cases perfectly harmless, does, for a limited time, give almost perfect security against the contagion of variola."

In a report of Dr. Smith, of New Jersey, in 1858, he comes to the conclusions in regard to the protective power of vaccination which so nearly agree with my own, that I copy them.

"1st, That a *perfect vaccination* affords *perfect protection* from small-pox during life, and that if this is done in all instances soon after birth, small-pox may, as Dr. Jenner supposed it would, be *eradicated*."

Again: "That the common idea, that, the sorer the arm from vaccination the better the protection, is a mistake, and that a very small pustule which goes through the regular stages and produces a constitutional effect about the ninth day, is more generally perfect than one that produces great inflammation, pain and swelling, and affects the glands. Indeed, I am always suspicious of a case when this occurs, and take an early opportunity to revaccinate, and have often had my suspicions verified by a good pustule."

Dr. Francis Condin, the author of a work on Diseases of Children, says:—

"The evidence which has been accumulated in proof of the complete protection against the variolus contagion conferred upon the human subject by effective vaccination is too overwhelming and positive to admit of the possibility of doubt or cavil, and when cases of small-pox occur in persons said to have been vaccinated, it is evident that from some cause or other, the vaccination was an entire failure, or effective to only a partial extent."

Dr. Condin, after an investigation of many years as to the failure of vaccination to completely protect the person vaccinated, comes to the conclusion that "in the majority of such cases, the failure is able to be traced either to the employment of spurious matter, or through the fact that those operated on receive only partial vaccine infection from deterioration of the virus prior to use, or from an inefficient method of using the virus."

There are several causes by which vaccine-matter may be rendered ineffective or effete. After a genuine and perfect vaccine vesicle has been produced by the introduction of the most unexceptional virus, its regular course may be interfered with by some accidental irritation and simple inflammation set up, causing the vaccine lymph to become mixed with ordinary pus globules. Should the lymph formed in such a case be made use of for vaccinating, a sore arm will generally occur; but either no vaccine infection of the organism will be produced, or only to a limited extent insufficient always to insure complete and

permanent protection from various poison. A sore arm produced in this way has been not unfrequently mistaken for that of perfect vaccination: and such individual, reported to be protected from small-pox is sent forth to encounter its contagion with the liability to an attack of small-pox or of so-called varioloid disease. Therefore the protective power of vaccination is brought into disrepute, and the anti-vaccinationist is furnished with an argument against the protective power of vaccination.

There seems to be a medium effect in the action of the vaccine material which vaccinators esteem to be the most desirable, and, other than that, the protective power obtained therefrom is more or less defective.

I have referred to the too severe effect. I would now say that the deficiency of vaccine protection may be caused by too slight an extent of vaccine infection imparted to the system. This may be produced by the employment of effete matter, or virus that has lost from some cause its specific qualities; exposure to atmospheric heat or cold of too high or too low degree, may be cause of failure in the effect of the virus; and it is asserted by some observers that through a long series of transmission of virus without retro-infection through animal transmission, the infective power of the virus is impaired.

Dr. Gregory says, of the deterioration of vaccine virus, "This idea was never countenanced by Dr. Jenner and is not generally believed by medical men, but it is the favorite doctrine with the public. So far from believing in any deterioration of virus from successive inoculations, there is reason to believe that by careful selection of well predisposed children the pock may even be restored from an imperfect state, and by proper care, therefore, may be indefinitely retained in that condition."

Dr. Gregory specifies as sources of failure in complete protection by vaccination, the following causes: "1, spurious matter; 2, insufficient number of vesicles; 3, preoccupation of the skin by other diseases, such as tetter, ring-worm, erysipelas, etc.; 4, robbing the vesicle of its contents, as when vaccination is done from arm to arm; 5, external violence done the vesicle in its early stages by rubbing or scratching, etc." Of all these, the character of matter and the method of operating are the greater causes of failure.

The character of the virus at the present day is only to be considered under the heads *bovine* and *humanized* virus.

The use of humanized virus is usually known at present as the Jennerian method of vaccination, and under this method vaccination obtained its reputation. Its protective influence extended over the world, and was practiced from arm to arm. There was little controversy as to loss of power in virus for more than thirty years. But through traffic in vaccine virus, of late the reputation of original Jennerian, or humanized, virus has been more or less imputed to have lost its powers, and therefore several methods of renewal have been adopted to increase the power of the humanized lymph. The most extensive method has been that of retro-vaccination; that is by the introduction or inoculation of humanized virus into the animal and then using the lymph thus produced under the name of "*bovine virus.*"

This virus thus produced was supposed to be strengthened or renewed in its special protective power. Most physicians used for many years a small quantity of virus obtained from dealers in matter obtained in this way, as a starting point from which, by selecting virus from some exceptionally healthy child, they would continue a practice of vaccination indefinitely. The virus obtained by retro-vaccination was esteemed more for its convenience as a source of supply than as a matter of a superior quality.

Probably the most extensive operator in retro-vaccination in this country up to 1866, was Dr. Ephriam Cutter, of Woburn, Mass. He contracted and furnished large quantities of vaccine virus to the United States for use in the army during the late war.

The virus he used in vaccinating cattle from which he obtained crusts, was originally obtained from the vaccine vesicle on a child, and was reproduced in the kine. From this start, by continued retro-vaccination he obtained virus from more than a thouaand cattle. He subsequently made a report to the American Medical Association upon the production of vaccine virus (1872.) Some of the conclusions he arrived at were:

1. "Vaccine virus has been developed in this country by inoculating kine.

2. "Vaccine virus has been reproduced

by retro-vaccination in this country with success.

3. "The spurious cow-pock first described by Jenner is frequently observed in this country.

4. "The natural non-humanized cow-pock is endemic in this country, and only needs looking up to be discovered.

5. "It is therefore unneccessary to levy foreign countries for such virus.

6. "Except as regards purity from syphilitic taint, the virus from the cow has no special claims above the carefully selected humanized virus in ordinary use. But the resort to animal vaccination gives opportunity to procure at all times a supply of vaccine almost unlimited in quantity."

The Beaugency cow-pox virus, from which a renewal of the "stock" was made in Europe and introduced in its purity into the United States, was discovered in April 1866, by a French physician, Professor Depaul. Dr. H. A. Martin imported the virus from the "stock" in 1870. The virus brought to America was from the 258th, 259th and 260th animals of Dr. Depaul's series, beginning with the heifer of Beaugency. It is generally supposed that since the introduction of this virus into America it has been perpetuated through animal transmission to the present, and in a measure constitutes the material from which the majority of vaccine virus is offered by the producers on the different vaccine forms of this country.

There has been much discussion as to the use of bovine virus *direct* and the bovine virus of *long humanized variety*.

In an article written by Dr. S. C. Martin and published in the *Boston Medical Journal*, Dec. 16, 1885, the writer makes the assertion that, "It is no longer possible here to observe the effects of long humanized virus. There is probably now none of it in this country; that which passes under that name being but a few human removes from the cow." This assertion drew forth a controversy between Dr. Chapin, of Providence, R. I., and Dr. S. C. Martin, in regard to the possibility of obtaining long-humanized virus for the purpose of comparing the merits of the two kinds. Dr. Chapin says: "I desire to call your attention to the fact that humanized virus has been used continuously by this department (The Health Department of Providence, R. I.,) since 1856, (over 30 years.) The stock has been maintained by continuous transmission from child to child, without being once renewed from the cow; and tradition says that the virus first used in 1856 was of Jennerian stock introduced into this country by Dr. Waterhouse. As a support of the belief in this tradition I introduce the following:

"Dr. E. M. Snow, Superintendent of the Department of Public Health at Providence, writes, March 1883, 'The practice of vaccination was introduced into New England by Dr. Benjamin Waterhouse in the summer of 1800, about three years after the discovery of Dr. Jenner. Physicians generally adopted the practice and there were some persons, not physicians, who made a business of vaccination, travelling about the country for that purpose. Among these was Artemus Stebbins who, when 18 years old, in 1806, lived with Dr. Waterhouse and learned the art of vaccination. He made it a business for life; travelling extensively in three of the New England States, vaccinating for a small fee. He told Dr. Snow not long before his death, that he had vaccinated over 138,000 persons. Sylvanus Fancher likewise learned the art of vaccination of Dr. Waterhouse, and in 1810 was employed to vaccinate the people of Providence. He vaccinated 4,305 persons and was paid by the town $233.25 including six weeks board at $3 per week, recciving therefore exactly five cents each for those vaccinations.' Subsequently the plan was adopted of weekly vaccinations made at the Health office, with a record of all vaccinations performed. In 26 years there were 28,365 persons vaccinated at that office, an annual average of 1091." These were all done with what is supposed to have been the Jennerian stock of long-humanized virus and Dr. Chapin says, in 1885, "nearly 47,000 persons have been vaccinated with this virus here and our experience has been that while it is certainly not inferior to the bovine virus in protective power, it is decidedly superior to it in that it is much more certain to 'take' than any animal virus we have been able to obtain."

In 1887, Dr. Welch, of Philadelphia, says, "From hospital experience I believe that vaccination has absolute power of preventing small-pox. He preferred humanized virus." Dr. Day, author of

Diseases of Children, says, "I prefer vaccination from arm to arm."

Dr. Welch, in Hare's Practical Therapeutics, writes—"I have never been able to succeed well with animal lymph. It is too unreliable, and when it does succeed in inducing vaccinia, the process is usually so slow that it does not reach the stage at which protection is exerted, before symptoms of small-pox appear. I know of no virus that is more reliable or will give better results than eight-day lymph, taken directly from a typical vaccine vesicle on the arm of an infant—but this virus can seldom be obtained when needed for the purpose; next to it I prefer humanized virus in the form of crust from a healthy infant, and I have a very decided preference for that which has resulted from a long series of human transmissions."

New York Medical Journal, May 31, 1884, Page 614, says: "Dr. M. F. Bassett, of Quincy, Ill., before the Illinois State Medical Society, read a paper in which he took the ground that humanized virus had been shown by long experience to be preferable to bovine virus. For his part he preferred that those of his patients who refused to be vaccinated with the former should bear the responsibility; for he would not use the animal virus."

In an article on vaccination, Dr. Walter F. Atlee, of Philadelphia, (*American Journal of Medical Sciences*), quotes a Dr. Stevens, of the Medical Department of Local Government Board, as saying, in relation to the supposed deterioration of humanized vaccine lymph in his country, *apropos* of the question of animal vaccination. "He believes that he has examined more vaccinated children than any man alive, or who ever lived. He finds no ground whatever for the suspicion that the present arm to arm lymph has lost its true and original Jennerian character. He denies it altogether and says, 'I do not believe that our arm to arm lymph affords any less protection than it ever did."

Dr. Atlee of Lancaster, father of Walter, says, "I fully agree with Dr. Stevens. He says he has studied the disease and its effects with extreme care, from 1818 to the present time (1880, over sixty years,) and I find now no difference in its appearance or in its preservative effect from what they were at the first." Dr. Atlee continues, "My father adds, 'I have in almost all instances used the crust, sometimes have punctured the vesicle and taken the lymph on glass. In a few, very few, instances among the thousands I have vaccinated, I have taken it from arm to arm. But I never could perceive any difference and I believe one is no better than the other, each producing all the well-marked diagnostics of genuine vaccine pustule.'

"I have tested the efficacy by inoculating for small-pox after vaccinations, have taken patients after vaccination to cases of malignant small-pox in small and hot stove rooms and exposed to the foul atmosphere for fifteen or twenty minutes, secure from danger. In one case, of a mother with six unvaccinated children, one at the breast, who had a severe attack of small-pox, as soon as I discovered the nature of the case, I vaccinated all the children from a vaccine crust and they all took the vaccine disease; the room, it was in February, was a small ten by twelve foot room with a hot ten plate stove and but one bed, on which they all slept and which was saturated with small-pox contagion, yet these children picked off the scabs from their mother's body and the baby nursed at her breast and no one took the small-pox. Had I time this morning I could multiply instances of this kind. I have the utmost confidence in the protective power of vaccination and I feel very sure that the cases of failure are very much more attributable to the use of vitiated vaccine matter, to the ignorance of unprofessional persons as to the purity of the virus, who have practised vaccination and, in my experience, to the carelessness of physicians themselves as to the conditions of the patients vaccinated." The above tests reported by Dr. Atlee can no doubt be duplicated by physicians present, and with the multiplicity of such evidence it is strange that any person should doubt the protective power of vaccination.

The kind of virus employed or recommended at the present time is largely in favor of what is termed *direct bovine virus*. With this recommendation I must say that I differ, and when I can get good humanized virus from the arms of healthy children, whose health record extends back some two or three generations, I much prefer such. I must therefore acknowledge that I am "*a barber*," according to a recent

writer who advocates the use of animal virus. He writes, "It is pleasant to note the progress that has been made in the use of animal virus; with the exception of *barbers*, there are, at the present, very few who do not use it in preference to humanized virus."

From my experience with the two kinds of virus, I attributed most of the severe sore arms, of phlegmonous, erysipelatous or septic character, to the use of improperly charged animal vaccine points, and I am supported in my opinion by many writers upon the subject of vaccination. These sore arms constitute one of the stray objections to being vaccinated at present.

In a discussion upon this subject and the difficulty of obtaining pure and efficient animal virus. (*Boston Journal*, March 15, 1883), Dr. Martin made startling statements concerning the traffic in this commodity, viz: "Material which ought to be thrown away, crusts, epithelium, etc., is mixed with glycerine to form a paste. This costs almost nothing and sells at an immense profit. The virus at Titusville, Georgia, affords a case in point. It costs but a cent a patient, and the public vaccination was intrusted to a 'cancer doctor.' Horrible results followed, the virus took so thoroughly that the victims had to go to bed. "Extensive axillary abscesses in some cases were but a small part of the mischief. Such practice as this and other instances, has brought reproach upon animal virus which it can hardly stand up against."

A physician, whose advice was given to the public recently in our daily papers, says: "Be sure and get fresh bovine virus. It should not be over ten days old, as after that period its vitality is uncertain. Use no scab or lymph from a child or other person." This advice evidently comes in as contradictory of most of the authorities I have quoted, and agrees with the attempt to prove superiority in quality and effect which the dealers in bovine virus wish to impress upon the people. This advice is, as I believe, mostly to the advantage of the trade and against almost all the opinions of experienced vaccinators.

Humanized virus and animal virus may be preserved indefinitely in all its vigor and purity by several methods. I have been accustomed for many years to keep myself supplied with vaccine crusts taken from healthy children at about the twentieth day, by embedding them in small blocks of white wax, perfectly sealing them over the heat of an alcohol lamp and laying them away for future use. I know that virus preserved in this way retains its specific infection for years. In 1885, Dr. C. H. Preston was desirous of vaccinating some children. He came to me to obtain some virus. I gave him a portion of crust which I had enclosed in wax in 1882, three years before. He used the same and reported a perfect result, and returned to me a characteristic crust from a child he had vaccinated with it. I exhibit the crust to the members present, together with a crust which I put up in 1882, showing a comparison of the two, from which comparison you will see that there is no evidence of loss of power. I find the following published in the *New York Medical Jour.*, July, 1884, page 84—under the title, Activity of an Old Vaccine Crust: "A remarkable instance of the preservation of the activity of a vaccine crust, is related in a recent issue of the *North Carolina Med. Jour.* It seems that during the term of office of the Hon. Willis Alston (grandfather of Dr. Alston) as a Congressman from North Carolina from 1803 to 1825, Dr. James Smith, of Baltimore, was director of the vaccine institution for the State of Maryland. He sent to Mr. Alston a package of vaccine, and it remained unopened until it fell into the hands of his grandson, Dr. Alston, in May, 1869. It was a crust embedded in wax and enclosed in a wooden box. Dr. Alston vaccinated his servant with a part of the crust, and in due time it took effect, leaving a well defined scar." With vaccine crusts preserved in this way by any physician and kept on hand, he is prepared to vaccinate persons who have been exposed to this contagion, at the shortest notice, or in any emergency. To thus use the vaccine crust I can see no objection.

Dr. Wm. M. Welch, Physician-in-charge of Hospital for Infectious Diseases at Philadelphia, March 24, 1894—after a a service of twenty-three years—says: "I am firmly of the opinion that if all persons were properly vaccinated in infancy, and again at the age of puberty, Jenner's prediction as to the power of this agent to extirpate small-pox from the globe, would be realized. And I would add small-pox could only be found when we are able to *navigate the aerial space and reach the stars.*"

CONTRIBUTIONS TO OBSTETRICS AND DISEASES OF WOMEN.*

[NUMBER TWO.]

THEOPHILUS PARVIN, M. D., PHILADELPHIA.

CURETTING THE UTERUS AND AMPUTATION OF THE LIPS.

Mrs. —, about thirty-five years of age, has given birth to three children at term, and since her last labor has had three miscarriages. One of the latter ended at about six months, and the product expelled presented that form known by the old authors as a fleshy mole; another occurred at the end of the third month of pregnancy, and then too, a fleshy mole was expelled. I attended her in each of the last two miscarriages.

After convalescing from the third abortion, she consulted me for leucorrhœa, pain in the right side, back ache, and especially with the hope that something could be done to prevent the recurrence of the accident from which she had thrice suffered. I found the uterus by the sound to measure a little more than three inches, no eversion of the cervical mucous membrane, and a bilateral tear of the cervix, the anterior lip mitriform, but the posterior somewhat broader and shorter.

Menstruation was quite regular, and neither profuse nor painful.

For a few months I treated her with local applications of iodine, etc., and had injections of creoline and hot water used daily. There was some benefit, but no cure.

I then, the patient of course being anæsthetized, and the external parts being thoroughly disinfected—by soap and warm water externally, followed by vaginal injection of a solution of carbolic acid—curetted the uterus, injected Churchill's tincture of iodine, and amputated a portion of each lip. After excising a wedge from each lip, the gaping surfaces were brought together by silk-worm gut sutures—not having at hand any sterilized cat gut, which of course is the preferable material in such operations—all the steps in the operation being taken under continuous irrigation of the parts with a three per cent. solution of carbolic acid. In the curetting a Martin's dull curette was used, and the iodine injection made with Braun's syringe. She was in bed ten days and the stitches were removed.

In six months after the operation she became pregnant, passed through her gestation without any serious discomfort, and without the slightest threatening of miscarriage, or of premature labor, and gave birth at the normal period to the largest child she had ever borne, the labor briefer and the suffering less than in any of her previous experiences. Both she and her child have remained, now several months, quite well.

Reflections.—Some two years ago I published a study of fifty-four cases of molar pregnancy, several of them being furnished me by my friend Professor Winckel, chiefly from the records of the Munich Frauen-Klinik: these were all instances of the expulsion of a fleshy mole. In that study I came to the conclusion that the affection was in most cases caused by disease of the chorion. This view I am inclined now to doubt, and believe the disease is primarily in most cases, in the decidua, and the affection of the chorial villi is secondary. It seemed to me, therefore, that the best way, the only right way in short, to prevent this patient from having miscarriages was to have a healthy lining membrane of the uterus. Having failed by the more common treatment of the uterine catarrh, catarrh of the body not of the neck, I employed the curette, and followed it by the injection of a solution of iodine. I know that the curette is condemned by some, and that grave accidents have occasionally followed its employment. But were the cases in which accidents followed such as required this treatment, and were necessary antiseptic means used in the operation? I have curetted in many cases of endometritis, and have never met with unpleasant consequences.

I have rarely found a case in which previous dilatation, either gradual or instantaneous, was necessary, for the discharge generally keeps the canal sufficiently patent to prevent this preliminary of some.

The proper treatment of a torn cervix can

not in all cases be settled by an appeal to the brilliant operation devised by Dr. Emmet. In some cases his cervicoplasty gives all that can be desired. But if there is present with the tear of the neck an endometritis, the operation for the former does not cure the latter—nay, makes the interior of the womb less accessible for therapeutic agents. An operator once told me that he so perfectly restored the cervix that the os, though the woman had borne several children, could not be distinguished from that of a virgin. Now this is not nature, and I have more than once had greater or less difficulty in consequence of such perfect restoration, in treating a diseased endometrium.

Further, suppose that in a bi-lateral laceration there is hypertrophic elongation of the lips, there will be after cervicoplasty a cervix of more than normal length, a condition which is evil rather than good. I am satisfied that in some cases of tears of the neck of the womb amputation is preferably to paring and stitching. So too, such amputation, or excision of a portion of the lips is preferable to Sänger's substitute for Emmet's operation. In Sänger's method the flaps dissected on each side of the rent remain attached to each other at the apex, and each flap is attached at its lower part to the cervix; then the denuded surfaces are stitched together. The flap is thus pushed downward by the approximated borders as the sutures are introduced from above below, and this inevitably results in a greater or less projection of tissue at the base of the united tear.

But without any further discussion of the treatment of endometritis and of tears of the neck, in regard to the case that has been reported, the result is to my mind, sufficient proof, as it will be I think to the minds of others, that the plan pursued was appropriate.

NOTES UPON THE ELIMINATION OF URIC ACID.

W. H. WALLING, M. D., Philadelphia, Pa.

It seems to be the accepted opinion that the pathology of uric acid is more a matter of defective elimination than of excessive formation. The physiology of the subject, however, is not yet settled. Indeed, much remains to be learned regarding the question. Some writers suppose that the defect lies in a functional disorder of the liver. Others on the other hand, contend that lithemia has little or nothing to do with disturbance in the function of the liver, and that it has not been shown that uric acid is the only, or the chief agent in producing the symptoms.

Osler says, "That certain symptoms arise in connection with defective food or tissue metabolism, more particularly of the nitrogenous elements. This faulty metabolism if long continued, may lead to gout, with uratic deposits in the joints, acute inflammations, and arterial and renal disease."

This statement seems to contain all, or nearly all that we know of the physiology of lithiasis, which is really very little.

The substances mostly relied upon to eliminate uric acid from the system are the alkalies, such as the salts of lithium and sodium, the various salicylates, and latterly a preparation called piperazine. From some experiences with the latter substance, it would seem that the simple solution of the acid is not all that is to be aimed at. Perhaps, however, I have not given it sufficient trial.

Regarding lithia, Haig says: "Though a beautiful solvent of uric acid in the test tube, yet when given to the human subject by the mouth it never reaches the uric acid at all, because it at once forms insoluble compounds with the phosphate of soda in the blood, thus removing from that fluid one of the natural solvents of uric acid, and diminishing its power of holding uric acid in solution." This is in direct opposition to the generally expressed opinion regarding the use of the lithium salts in the uric acid diathesis.

I have for a long time been dissatisfied with the results obtained from the use of lithium in lithemic conditions, and more especially where there were effusions around the joints, with other symptoms connected with what is commonly regarded as being due to a so called excess of uric acid.

Furthermore, not getting the desired results from simply stopping the apparent excess by the use of substances claiming to effectually remove such excess, I questioned still further, the commonly accepted theories, and was finally led to adopt an entirely different line of treatment. This was done by dropping all the so called anti-lithics, and in relying simply and solely upon a single remedy, and that was a preparation of cascara sagrada. Repeated trials have convinced me that the faulty metabolism is more quickly remedied with this drug alone, than with any other, or combination of others, thus far experimented with. Just how it does it I may be unable to make clear, even to myself. In fact, I do not try to, but in a number of instances I have demonstrated the fact to my own and the patient's entire satisfaction. This has been sufficient.

One case only will be mentioned, as it is typical of others, and will illustrate my statement as well as a dozen or more.

Mrs. G., aged fifty-five, has for years, according to the history, been the subject of uric acid storms. Being of a naturally robust constitution, she withstood these fairly well, apparently making quick recovery. As time wore on however, the results began to be more manifest in enlarged and very painful joints, as well as showing other symptoms peculiar to this diathesis. The usual remedies were administered and applied with some amelioration of the symptoms, but without getting the desired relief. After exhausting all the commonly accepted remedies without avail, I commenced the exhibition of the aromatic fluid extract of cascara sagrada, made by Parke. Davis & Co., in ten drop-doses to fifteen drop doses, two or three times a day as the case demanded, finally settling down to one single dose at the close of the day. Active catharsis was not aimed at, but a gentle laxative effect was constantly maintained for a prolonged period. The effect was not at once apparent, but within two weeks there was a marked amelioration of the aggravated symptoms, and in four weeks time the swollen joints had almost resumed their normal appearance, the soreness having nearly disappeared. At this writing, [nearly two months having elapsed,] there is no complaint whatever, but I directed the remedy continued. No change was made in the diet in this case, as I desired to more fully test the remedy, and am fully satisfied that the good results were due solely to the cascara. I may add that I have tried other brands of cascara, but they have not been satisfactory, hence I have come to regard the fluid extract above alluded to, as the only one upon which I could confidently rely. It never fails, hence my prefcrence for it.

This extract is an invaluable intestinal tonic in chronic constipation, and other disorders of digestion. The dose must be regulated to suit the case. Ten to twenty-five drops, once, twice, or three times a day, as may be required, given in water or milk, either hot or cold, as may seem best, but I prefer the hot diluent. I find that it is better to give it about an hour before meals, or at bed-time. The extract as now prepared, is very palatable, being entirely devoid of the old-time bitterness, so characteristic of many preparations of cascara. I have also found it difficult, at times, to get the article prescribed, hence frequently purchase it at the wholesale house, and dispense it myself. In this way there can be no substitution.

The Acid Treatment of Jaundice.

Dr. M. Alivia, of Viterbo, at the recent meeting of the International Medical Congress at Rome, read a paper on this subject. He based his treatment principally upon the fact that there is present in jaundice a general diminution of acidity in all the fluids of the body. The contents of the stomach show generally an alkaline or neutral reaction, and contains very little, if any, hydrochloric acid. The urine is often alkaline, and contains more chlorides and aromatic products, but less urea, than normal urine. The acids of the bile are reduced, which occurrence probably depends upon stasis of bile in the liver. Under acid treatment the stomach contents and urine soon regain their normal reaction, while the chlorides and aromatic compounds are reduced, with a corresponding increase in the quantity of urea.

Dyspepsia and Tuberculosis.

Prof. Hayem, of Paris, has recently shown that there is a marked association between dyspepsia and tuberculosis in a great number of cases. The disorder most commonly present is simple gastritis. As the digestive disorder usually occurs first, and paves the way for the pulmonary disease, it is important that disorders of digestion should receive prompt attention.

COMMUNICATIONS.

OVARIAN TUMORS.*

L. S. MCMURTRY, M. D., Louisville, Ky.

The subject that I want to introduce to the society this evening is one which it occurred to me would be of interest to all the fellows,—a very common condition, that of ovarian tumors. Mr. Tait has said that the last words had been spoken upon this subject, when he had reported 134 consecutive ovariotomies between two deaths, stating that the operation was the most successful major operation known in surgery. It is an operation that interests everybody, because ovarian tumors are the most common of all tumors of the pelvic organs, and there are still some points in this connection that deserve attention.

In the first place the mortality has been reduced in ovariotomy mostly from the fact that the operation stands so very well with the profession and with the laity that the surgeon is consulted very much earlier than in former years. It has only been within a few years that a number of fallacies have been completely and entirely refuted in regard to these tumors. If we take the old masters' statements in this branch of surgery, we find that such eminent surgeons as Peaslee and Sir Spencer Wells advocate as one of the steps preparatory for ovariotomy, that the patient ought to be allowed to become emaciated, as it prevented inflammation afterward. This will be found in Peaslee's work on ovarian tumors, and also in Sir Spencer Wells'. That fallacy has been completely refuted, and the mortality has been reduced just in proportion as the operation is done early. It falls to the lot of every practitioner of medicine to meet these cases of ovarian tumors, and just as the diagnosis is made more easily and accurately and operated upon earlier, has the mortality been reduced.

In regard to the operative technique, there is very little to be said. I do not believe the profession now considers either the long or short incision as having a great deal to do with the mortality. The older ovariotomists thought this a very important factor. The most important thing in relation to ovariotomy is to see the patient early while she is in good condition for operation; next properly preparing the patient for operation. The latter is of far more importance than any other single feature connected with it. After putting the patient to bed for some days before the operation, she should be thoroughly purged and fed upon very light diet so as to get the intestines empty; by this means the operation is facilitated and convalescence is accelerated.

I want to illustrate a few points with a tumor I removed last Saturday from a young lady nineteen years of age, the daughter of a physician, which grew to very large proportions. It is a multilocular cyst. The fluid in one part of the cyst is so thick that it will run through a trocar. There are two large and several smaller cysts, the mass being so great that it pushed the abdominal viscera tightly up against the diaphragm causing serious interference with the respiratory functions. Aspiration was practiced on several occasions when the tumor reached such large proportions, refilling shortly afterward. On three occasions the young lady determined to have the operation done, and went to the train to come here for the purpose, and three times went back home refusing. She came here once and just on the eve of the operation backed out again. Meantime the tumor continued to increase in size; this was nearly two years ago. She became very much emaciated, the tumor was very large and she was finally persuaded to consent to the operation.

Ovariotomy was performed last Saturday morning, and convalescence has been uneventful and easy. The tumor had attained such enormous size that it necessitated an incision through the umbilicus. The pedicle was very broad but ligation was comparatively easy. The other ovary

*Read before Louisville Clinical Society, March 13, 1894.

was found to be cystic and was also removed.

There is another point in regard to treatment of these tumors or abdominal section for any condition which I would take occasion to mention in this connection, and that is the fact that we can entirely abolish the use of opium. I believe this can be done in the majority of instances, and I believe it to be due more than anything else to the fact of the introduction into this department of surgery of skilled nursing. Every case of abdominal section will require an opiate without a competent nurse, and after the opiate has been given a great deal of nursing will be required; but by the attentions of a good nurse in assuring the patient, in bathing her hands and head, changing her position and encouraging her in every way to do without it for the first twelve or twenty-four hours, its use can be avoided.

In the case I have just reported, not a single dose of opium was administered, her pulse has never been above 84 and she is making an ideal convalescence.

In regard to the diagnosis of these tumors: It is very common for physicians in general practice and for surgeons also to be severely criticised by the laity for failure in diagnosis. I know it is very common when a physician refers a patient to the surgeon, and it is reported after they reach the city that the condition is an ovarian tumor which was not previously diagnosed by the physician, that he is severely criticised. They go so far as to say that the physician did not know what it was, but when the patient reached the hands of the surgeon he found it to be ovarian tumor and removed it. I think it is the duty of everybody to promulgate among the laity the fact that nobody can make a diagnosis absolutely of ovarian tumor in certain cases. I will refer to a case that I reported to this Society last July in which three very superior practitioners and surgeons had diagnosed the case to be an ovarian tumor. When an incision was made in the abdomen the tumor was found to be a large cyst of the left kidney, and a nephrectomy was immediately performed. So the diagnosis of these tumors becomes a matter of very great difficulty, and the only diagnosis that is absolutely perfect is an incision through the abdominal walls.

FIBROMA OF THE UTERUS.

No. 2—This tumor, which you will see is a fibroma of the uterus, was removed this morning. And in this connection I will make a continued report at the last meeting of this Society at which time I exhibited the specimen and also a photograph, showing the peculiar conformation of the tumor.

The patient has made an uneventful and uninterrupted convalescence; she is now sitting up and practically well. It was only a short time ago that the profession was taught that fibromata of the uterus was harmless; that they amounted to almost nothing; they were treated with ergot, etc., I believed to be greatly benefitted; electricity was also used, patients were often told that the tumor would go away at the menopause without treatment. Perhaps they did—I say perhaps they did, because I formerly believed more than I do now that they did go away spontaneously; but it must be remembered in every case where the surgeon or physician makes the observation that these tumors disappear spontaneously, that the diagnosis is never perfected. The only cases of that kind which are reliable are those in which an exploratory incision is made and the tumor not removed, and it afterward disappears. In the early stages of these growths when the tumor is not large and degenerative changes have not taken place, the removal of the uterine appendages is a most satisfactory operation. A number of cases I operated upon five years ago, which are still under observation, removal of the uterine appendages has caused the tumor to shrivel up so as to cause practically no trouble. Treatment by means of electricity has been pretty generally abandoned, as experience has proven that it does not cure. When the tumor has attained the size of the one shown here to-night, pressing upon organs causing distressing symptoms, the proper procedure is to remove it; then again these growths are very prone to undergo malignant degeneration. I have operated upon several cases where I thought I was dealing with a simple fibroma, when examination showed that sarcomatous change had taken place.

In regard to the operation itself: I am perfectly satisfied that the exact technique of the operation will always vary, different operators having their favorite way of deal-

ing with the tumor. Dr. Cartledge has just expressed his preference for the intra-peritoneal treatment of the stump, cutting down to the cervix itself, and applying a direct ligature to the uterine and ovarian arteries. We all recognize that the greatest danger in the operation of hysterectomy is hemorrhage. The tumor leaves a stump that is composed of muscular tissue, and after the anæsthetic is eliminated by the patient this muscular structure is very liable to undergo contraction and the ligature may slip off from it.

I believe that in the extra-peritoneal treatment of the pedicle, we have the easiest, surest and safest method of dealing with these tumors. We must not lose sight of the fact that the greatest danger is from hemorrhage. Dr. Cartledge in his remarks has alluded to a method which embraces the real secret of the operation —to deperitonize the tumor and enucleate it, leaving the peritoneum, stripping off the bladder in front and the rectum behind, putting a *neude* around the pedicle with the peritoneum included, then you have everything outside the peritoneum when the incision is closed. By this method the field of operation is brought entirely out of the abdominal cavity, and the tumor can be treated just the same as a growth upon any other portion of the body.

The operation in the case I have reported was difficult because the pedicle was so short. The pedicle ought to be very small, and the greatest objections that have been found to the extra-peritoneal method of treating the pedicle with the *neude* is that it leaves a large slough. This tissue is very easily broken down, and even large quantities of it can be included in the *neude* with the pedicle without causing any trouble. In every case where I have used the *neude* there has not been a drop of pus, and no moisture at all, just a dry caries or mummification of the pedicle, leaving a granulating surface.

Considerable advance has been made within the last two years in the operative treatment of these tumors, and in case it comes up in the discussion, I could present cases that would leave no doubt in the mind of anybody concerning the fatal character of these growths. I have in mind one lady in this city who was in bed with feet and legs œdematous, great pain, vomiting daily, and before operation she was practically in a dying condition.

Some of these tumors are slow in growing, others grow very rapidly. They destroy life and are serious conditions of disease. I have no doubt after the progress we are making, the results that will be obtained from operative treatment of this class of tumors within a year or two will be just as favorable as obtained in ovarian tumors. The results in all instances both in ovarian and fibroid growths depend more than anything else upon the time the case is operated upon; it should be done before the system has been exhausted, before emaciation has occurred, and before degenerative changes are established.

Thiol in the Treatment of Female Diseases.

Gottschalk, after using thiol for nine months, believes it to be as efficacious as ichthyol in the treatment of female diseases while its freedom from odor is a positive advantage. He first employed thiol in the treatment of parametritic and perimetritic exudations. He introduced tampons saturated in a solution of thiol in glycerine (10 to 20 per cent.) into the vagina, renewing every day or every other day. At the same time he applied to the abdominal wall a thiol salve of the same strength. The tampon causes a sensation of abdominal constriction, accompanied by an abundant vaginal secretion, which ceases upon the removal of tampon. Thiol applied to the skin produces effects similar to those of iodine, and after daily applications of the salve for six or eight days, it is necessary to wait a few days before continuing its use Gottschalk has seen extensive pelvic exudations disappear in a few weeks under the influence of this local treatment supported by the internal administration of thiol. In recent and chronic forms of endometritis he introduces into the utterine cavity, by means of a Playfair sound, small cotton tampons saturated in pure liquid thiol. These topical applications are painless and inoffensive. They do not excite uterine colic or perimetric inflammation, even when removed every two or three days. They are, however, sometimes followed by a slight hemorrhage. He uses powdered thiol in cervical erosions with the best results. The only objection to the remedy is its comparatively high price.

TRANSLATIONS.

THERAPEUTICAL SUGGESTIONS FROM FOREIGN JOURNALS.*

LACTIC ACID IN CERTAIN FORMS OF CHRONIC LARYNGITIS.

Prof. F. Massei (*La Semaine Medicale*, No. 32, 1894,) in that form of chronic laryngitis which is met with in those who use the voice frequently, as singers, actors, preachers, professors, etc., and which disease is notoriously rebellious to treatment, has obtained actual cures by spraying with 2 per cent. solution of lactic acid. To succeed it is necessary to spray the throat very often, from eight to ten times a day, for some time; at the same time one should not neglect the usual hygienic measures, and he also advocates electricity and tonics. It is best to use a spraying instrument which produces a fine jet of spray and not a too diffuse cloud. This treatment, though not infallible will often succeed, and it has the advantage of being easily carried out by any one. This remedy in a spray form is also useful in tuberculosis and lupus of the larynx if alternated with one of corrosive sublimate.

TREATMENT OF TUBERCULOSIS BY COPPER.

Dr. Luton (*Le Bulletin Médical*, No. 41, 1894), speaks highly of the salts of copper in the treatment of tuberculosis. It appears to be an especially valuable method when the disease is external and the lesions are not too far advanced. At a more advanced period this result is obtained with greater difficulty, though it may be assisted by surgical means, and in pulmonary tuberculosis a condition equivalent to recovery may result. It may be given either internally, hypodermically or be applied externally. Hypodermically injected there is observed to follow a local inflammatory reaction. Locally, one may use the following:

℞ Acetate Copper,.....0 | 03 (gr.ss.)
White Vaseline,.....30 | 0 (℥j.)

HYDRASTININE IN UTERINE HEMORRHAGES.

Dr. Kallmorgen (*La Semaine Médicale* No. 30, 1894,) has employed this remedy in eighty-six cases of uterine hemorrhage of various origin and followed the patients for two years and a half, with a view to the final and definite results. He employed the following formula:

℞ Muriate Hydrastinine,..... 1 | 0 (grs. xv.)
Extr. and Powder Licorice. q. s. for thirty pills.
Three pills a day.

These pills have been well tolerated excepting in occasional cases where they gave rise to painful contractions of the uterus or slight gastric intolerance. The hemostatic action varied according to the cause of the hemorrhage. In retro-uterine hematocele, of which he observed five cases, the results were particularly remarkable. Indeed, in all cases the sanguinous discharge ceased rapidly. Functional hemorrhages were second as to hemostatic effect. Out of twenty-five cases in eighteen the flow was definitely reduced to normal proportions, and the accompanying dysmenorrhœa was either cured or considerably improved. Here it was only administered during the menstrual period. One or two days before the appearance of the menses the patients began taking two pills a day; during the period three pills a day were given, until all flow had ceased. The remedy acted very well in hemorrhages after abortion fifteen times out of eighteen, and in lesions of the uterine appendages, three times out of four. The results were much less favorable in hemorrhage from chronic endometritis, beginning abortion, and worst of all, in hemorrhage from fibro-myomata. Finally in hemorrhages from cancer of the uterus it was wholly without effect.

PALMAR ECZEMA.

Dr. J. Braun (*La Semaine Medicale*, No. 30, 1894) recommends the following solution and salve in palmar eczma, of professional origin:

℞ Caustic Potash..... 1 | 0 (grs. xv.)
Destilled Water..... 2 | 0 (gtts. xxx.)

℞ Nitrate Silver..... | 25 (grs. iv.)
Lanoline.....20 | 0 (℥v.)
Liquid Vaseline..... 4 | 0 (℥j gtts. xv.)

* In charge of the Translator, F. H. Pritchard, A. M., M. D.

Touch the eczematous spots with a few drops of the alkaline solution and then apply, three times a day, the nitrate of silver salve.

URINATION AFTER LABOR.

Dr. N. Recht (*Revue Internationale de Bibliographie Medicale*, No. 9, 1894) in a thesis has made a study of micturition in the lying-in period. He comes to the following conclusions:

1. Urination after labor in the majority of cases, follows spontaneously.

2. Catherization is but exceptionally required; if it be necessary it should be deferred as long as possible.

3. It is only indicated when the bladder assumes abnormal proportions, or if retention occur.

4. Catherization is liable to expose one to two dangers: cystitis in spite of all precautions, and dependence of the bladder for a time upon the catheter.

ICHTHYOL IN EXCORIATIONS OF THE FEET.

Dr. Hertz (*La Semaine Medicale*, No. 32, 1894) in excoriations of the feet in soldiers, especially from pressure and friction of the shoes, has found a 20 per cent. solution of ichthyol to serve excellently. Under its influence the swelling disappears in twenty-four hours, and healing follows rapidly.

TREATMENT OF DIPHTHERIA.

Dr. Béla-Bathory (*Journal de Medicine de Paris*, No. 21, 1894) in diphtheria employs the following formula:

℞

Tr. Myrrh	4	o (℥j.)
Glycerine	8	o (℥ij.)
Destilled Water	200	o (℥j ℥ij.)

Children of two years or thereabout may take a teaspoonful every hour or two, those of three to ten years a dessertspoonful, and finally, those still older, a tablespoonful every hour or two. Local treatment may also be used at the same time, if thought necessary. The writer claims to have obtained very good results with this mixture. The tincture of myrrh has the peculiar property of destroying the ptomaines which pass over into the blood.

TREATMENT OF FAVUS.

Dr. Guladre (*Russkaja Medizina*, No. 5, 1894) has treated several cases of favus, with success as follows. After having first cut the hair short, he washes the patient's head once a day for five days with black soap. The sixth day he applies to his head a compress soaked with the following:

℞

Thymol	1 part
Chloroform	8 parts
Olive Oil	36 parts

Fix to the head with a dressing; repeat three times a day. After the softened crusts have loosened then epilate partially and rub with this mixture. After three or four weeks one may begin to rub the head with a mixture of two parts of iodine and one of glycerine, every day for a week. With ordinary measures a recurrence may be looked for in six to eight weeks, while with his method, he has not noted a recurrence in four months.

PRURIGO.

Prof. Petrini-Galatz (*Spitalul*, No. 8, 1894), in a lecture on prurigo, recommended in the simple form, local application of a salve, consisting of

℞

Vaseline	100	o (℥iij ℥j.)
Lanoline	20	o (℥v.)
Oxide Zinc		
Powdered Starch, aa	20	o (℥v.)

Also warm baths three times a week. Internally, arsenic.

TREATMENT OF OZENA, ETC.

Dr. A. Musehold (*Deutsche Medicinische Wochenschrift*, No. 20, 1894) in the treatment of ozena as well as in that of dry catarrh of the nose and pharynx, speaks very highly of the following formula:

℞

Pure Glycerine	70	o (℥ij ℥jss.)
Borax	20	o (℥v.)
Destilled Water	30	o (℥j.)

The physician sprays each nostril with about one ccm. of this solution and after a few minutes, removes the crusts, and then wipes the nasal and pharyngeal mucous membrane quite clean with cotton on a probe. The patient, provided with a cheap spraying apparatus for dense fluids, sprays his own throat twice or three times a day. With this treatment the odor will disappear in a few days, the crusts soon decrease, so that there will no longer be a necessity for the physician to clean the nose. During the first week clean the mucous membrane every day, then twice every two days, and finally at long intervals.

EDITORIAL.

THE DANGERS WHICH LURK IN MILK.

Ample provision is made in the economy of Nature for the care and sustenance of the young of all forms of animal life until such time as they are able to provide for themselves. As we ascend the scale in the animal kingdom, we note two things—the increase of dependency on the part of the young, and the corresponding increased specialization of means for supplying the necessary food and protection. In man we reach, at once, the highest form of evolution together with the greatest degree of helplessness of the newly born and the highest devolopment of specialized provision for its nourishment. Nature has furnshed the human species, in common with the lower mammalia, with a typically perfect food in the form of a secretion from the mammary glands—milk. This secretion, which varies in different mammals according to the nature of each, is the ideal food for their respective young offspring. Similar in composition, the milks of different species vary mostly in the relative proportions of the component parts; and milk has been one of the most important food products throughout the history of the human race.

Partly on account of the irresistible human tendency to attempt improvement upon Nature, partly as the result of the artificial conditions of life developed by civilization, largely because the exercise of the natural functions of motherhood has gone out of fashion, it has come to pass that the vitrified abomination with its rubber nipple has to some extent replaced the living gland, and the milk of the lower orders of mammals, together with the various preparations secreted by enterprising manufacturers of infant foods, has been substituted for the food provided by Nature—the one food suitable for infant man.

When for any reason it was deemed necessary to feed an infant upon some substitute for its mother's milk, the milk from the cow, the goat, the mare or the ass, (as best suited to the individual fed) was used with perfect confidence so long as the source of supply appeared healthy

and the milk itself was fresh. Investigation and analysis having demonstrated the chemical differences between various milks, efforts were made to overcome the differences and prepare artificially a food in all respects equivalent to the normal maternal product. These efforts, more or less successful, have on the whole proved unsatisfactory.

Of late years bacteriologists, in their indefatigable pursuit of microbic game, have discovered that milk, so long esteemed the unfailing friend of suffering humanity, in reality is one of the strongest supporters of the allied armies of bacteria which are incessantly waging nefarious war against human life.

There is no doubt but milk does contain great numbers of micro-organism. Especially is this true of the milk supplied to large cities, which generally contains bacteria and the like in almost infinite variety and inconceivable number. A large proportion of this milk supply is not delivered to the consumer before it is forty-eight hours old; meanwhile, the methods ordinarily taken to preserve the milk have not been sufficient to prevent the growth and multiplication of the bacteria.

The very name, bacteria, inspires the popular mind with a vague fear of impending disaster, and is most universally associated with the idea of epidemic diseases.

As a matter of fact, in the light of our present knowledge, the vast majority of bacteria are perfectly harmless, if not actually benificent. But it has been definitely ascertained that a few species are mischievous and even malignant.

The matter of importance then, is not so much to eliminate all bacteria, as it is to prevent the contamination of the milk supply by those agents which we know to be harmful. Man from the beginning has used milk containing bacteria and, generally speaking, has used it with impunity; and it would be absurd to condemn the use of milk because of the presence of bacteria, without definite knowledge that it has been exposed to probable contamination from the mischievous forms of bacteria.

It has been proved beyond reasonable doubt, that diphtheria and scarletina, typhoid fever and cholera have spread through milk. It is now likewise asserted that tuberculosis may be conveyed by milk. Milk is also to be held responsible for the occurrence of cholera infantum, summer diarrhoea and similar intestinal disturbances.

In the case of contageous diseases the infection seems to be directly due to the bacteria contained in the milk, whereas cholera infantum and other intestinal troubles are caused by the ptomaines produced in the milk as the result of the presence of certain species of bacteria, and not by the bacteria themselves.

Tuberculosis is now recognized as contagious, and viewed as such, certain observations of the disease acquire a new interest.

Authorities agree that the greatest mortality from tuberculosis occurs during the first two years of life; and is greater in the first than in the second year.

Heller's investigations show that of ten thousand living, there die of tuberculosis, under one year of age, two hundred and forty-five. Between one and two years, one hundred and fourteen; between two and three years, seventy-six; between three and five years, thirty-four; between five and ten years, fourteen.

In a recent discussion on tuberculosis, (*Food*) Billings stated that "Tuberculosis undoubtedly caused more death in civilized countries than any other single disease, and a much larger number of deaths were due to it than appeared in the statistics. It has beed supposed by Cornet and others, that tuberculosis is not inherited—that if anything could be trans-

mitted it was simply a predisposition to the disease—but more recent investigations indicate that the bacillus of tubercle may be transmitted from the mother to the foetus. Many cases of death of children under one year of age given in the mortality statistics as due to marasmus, inanition, etc., and a certain number of cases of still-born were probably connected with the tubercle bacillus. In fifteen cities in France for which statistics were taken, Petit reports one-third of the cases for debility and marasmus as due, directly or indirectly, to tuberculosis."

According to Whittaker "the upper half of the alimentary track (mouth, throat, œsophagus, stomach, duodenum and jejunum) offers an unfavorable site for tuberculosis. The limp follicles of the ileum and large intestine are the organs usually affected when the disease has its origin in the alimentary tract." "Primary tuberculosis of the intestine occurs oftener in children than in adults." "The cause is due to the feeding of young children from the milk of tubercular cows."

The disease which in adult life most commonly manifests itself in lesions of the respiratory system, devastates infancy by attacking the lymphatic glands of the digestive system. Infant mortality from tuberculosis, is startling. Even if the doctrine of direct transmission from the mother to the fœtus *in utero* be accepted —and the proof of inherited tuberculosis is not conclusive—the course taken by the disease would indicate the alimentary canal as the most probable point of entrance for the infection, with the natural conclusion that the food furnished the means of conveyance.

Again, the common occurrance of tubercular disease in cattle, the extent of which is not accurately known but may be surmised from a study of the reports of Health Inspectors, would appear to confirm the impression that tuberculosis is a very real danger incurred by the use of milk as a food, especially for infants. That it is a possible danger, cannot be doubted; but whether the danger be great or slight, at present, is unknown.

In the effort to emphasize the actual existence of such conditions and the disastrous results which are liable to occur because of their existence, the enthusiast for preventive medicine and the specialist who makes his observations under the peculiar surroundings of the laboratory, are apt to exaggerate the importance of the particular subject by obscuring modifying circumstances. The result on the people at large, is like that of incessantly crying, Wolf! When in every day experience they fail to see the animal materialize, they become indifferent to the warning until disaster is upon them. So that while we would abandon no measure of preventive medicine that promises to accomplish something, we believe that the medical profession should not endeavor to arouse popular alarm but, on the other hand, should seek to allay it by using rational measures for educating the people; and reason requires that due weight be given to matters of practical experience and every-day observation.

For instance, there is scarcely room to doubt that milk which contains the specific germs of typhoid fever, scarletina, cholera or diphtheria, has been contaminated from sources of the animal furnishing the milk, and that such contamination could be avoided by the exercise of ordinary care on the part of the owners. Indeed infection could take place only through criminal neglect or equally criminal ignorance.

Tuberculosis, however, exists in cattle in the same form in which the disease occurs in man, and the milk cow may be extensively diseased and yet continue to furnish milk. It seems probable that milk from tuberculous cattle will not contain bacteria unless tubercular foci exist

in the udder. Even when milk contains bacteria, tuberculosis it is not the inevitable result. The germ does not multiply in milk, though it may remain alive for some time. Experiments have shown that a number of these germs must enter the body at one time in order to cause the disease. When present in the alimentary canal and in sufficient number, infection cannot take place so long as the mucous membrane of the digestive tract is in a healthy condition. And when it has entered the system, the micro-organism has to survive the conflict with the phagocytes.

The case is different where the milk contains the poisonous ptomaines which cause cholera infantum and other intestinal disturbances.

The dangers which lurk in milk are no greater now, that they are recognized, and their results measured, than they were when their existence was not even suspected. The responsibility for their continued existence is in direct proportion to the knowledge we have concerning them.

BOSTON MEDICAL LIBRARY ASS'N MAY 11 1899

ABSTRACTS.

LIGATION OF THE BASE OF THE BROAD LIGAMENTS PER VAGINAM, INCLUDING THE UTERINE ARTERIES FOR FIBROIDS OF THE UTERUS.

Dr. Augustin H. Gœlet, of New York, in a contribution to the *American Medico-Surgical Bulletin*, June 1, reports favorably upon this operation in his hands for the control of uterine hemorrhage and reduction of fibroid growths. He believes it should be done in lieu of hysterectomy when that operation would involve too great a risk, and as a preliminary step with a view of avoiding the necessity of the more hazardous operation. When extensive attachments have not been formed which would afford additional nutrition, considerable reduction has resulted even in growths of large size. When the operation has been done for smaller growths the result has been more satisfactory. In some instances complete atrophy has been reported. This result, as well as arrest of the uterine hemorrhage, is accounted for by the diminished nutrition furnished the uterus and these growths by interference with the blood supply and nerve supply, which are included by ligation of the base of the broad ligaments. It is estimated that the uterine arteries furnish the uterus with two-thirds of its blood supply, and it is reasonable to expect that a profound effect will be produced upon that organ, and growths arising from the walls, if this is suddenly cut off.

The sole danger in the operation is the risk of including the ureters in the ligatures, as they pass down behind the uterine arteries only a half an inch from the cervix and are consequently in the field of operation. Dr. Gœlet suggests, as a preliminary step, to eliminate this risk, that bougies be passed into the ureters through the bladder. He admits, however, that a careful operator, accustomed to working in this region, may easily avoid the ureters.

The technique of the operation as described by Dr. Gœlet shows an important departure from the usual method followed. Instead of ligating each artery in only one place on a level with the internal os, he applies a second and often a third ligature to the artery on each side as it ascends along the side of the uterus, the result of which is to cut off the compensating blood supply from ovarian artery to the lower part of the uterus.

Dr. Gœlet gives all the credit of priority to Dr. Martin, of Chicago, who has recently suggested and popularized the operation and perfected its technique but states that he first ligated the uterine artery *per vaginam* on one side in January, 1889, in the case of a large fibroid the size of a seven months' pregnancy with a view of diminishing the size of the growth by reducing the blood supply. The artery on the other side was not ligated because the position of the tumor made it inaccessable. Six months later the tumor was one-third smaller, and was giving no inconvenience.

He quoted his last case operated upon to show how promptly uterine hemorrhage may be controlled by this operation.

SOCIETY REPORTS.

LOUISVILLE CLINICAL SOCIETY.

February 27, 1894.

[STENOGRAPHICALLY REPORTED BY C. C. MAPES.]

FIBROID TUMOR OF THE UTERUS.

Dr. L. S. McMURTRY: This specimen is a fibroid tumor of the uterus of rather unusual conformations. The growth weighed immediately after removal about six pounds. A great deal of pain was produced by its pressure upon the rectum, bladder and uterine appendages. The last tumor of this kind that I presented to the society, the Fellows will recall had no conformation favorable to the formation of a pedicle and I had to do a complete enucleation. In this case I succeeded in making a pedicle of the cervix and treated it extra-peritoneally with the *neude*. Both cases did so well that it is hard to say which method is preferable. This patient had no shock; did not lose over two ounces of blood in the operation, and her pulse never went higher than 90 after the operation. The *neude* came away to-day (the eleventh day after the operation) leaving a small granulating surface—a completely mummified button—healing by primary union.

DISCUSSION.

DR. W. O. ROBERTS: I would like to ask Dr. McMurtry which method of treating the pedicle he prefers in cases of this kind, and whether he uses the rubber cord?

DR. L. S. McMURTRY: I believe the extra-peritoneal method the safer. The great danger in the operation is from hemorrhage, and I believe this is reduced to a minimum by the extra-peritoneal method. I did not use a rubber ligature in this case.

DR. T. P. SATTERWHITE: Was not the tension on the pedicle very great?

DR. L. S. McMURTRY: The tension was very slight, and it can always be relieved by letting down the broad ligaments on each side.

PYO- AND HYDROSALPINX REMOVED FROM THE SAME PATIENT.

DR. W. H. WATHEN: I had intended to exhibit this evening quite a number of pus tubes recently removed, so as to compare them as to size, conditions, etc., but I had no time this afternoon to collect them; so I will only exhibit two tubes removed at three o'clock to-day. You will observe the larger specimen is a pus tube which was adherent in every part of its surface. It was removed from the left side. The other removed from the right side is a typical specimen of hydrosalpinx. More typical specimens of pyosalpinx and hydrosalpinx could not be found.

The patient was twenty-four years of age, married seven years ago. She was always well until six months after marriage. She then began suffering pain in the region of the pelvis and having profuse menstruation. From that time until now she has progressively grown worse, menstruation becoming more painful and lasting longer, sometimes continuing for three weeks. Her husband contracted gonorrhœa before marriage and the history of the case indicates that he infected his wife shortly after marriage. She had chronic endometritis; the uterus was greatly enlarged and the leucorrhœal discharge was profuse and offensive. Believing that many of the bad results or failures to make perfect cures in these cases is because the operation is not sufficiently thorough, and that septic matters and diseased structures are left that ought to be removed, immediately before removing the tubes, I dilated the uterus and thoroughly curetted it, irrigated the cavity with 1 to 4,000 bichloride solution, and tamponed the cavity and vagina with iodoform gauze. This hydrosalpinx had evidently been emptying itself into the uterus, because two months ago I examined the patient, and on the right side there was an enlargement considerably greater than at the time of the operation, and when the tube was ligated and removed close at the uterus, a considerable amount of the contents leaked out. The pus tube was patulous to the uterus and I cleansed the cavity of the tube left in the stump, and put

carbolic acid in it; then stitched over the peritoneal surface so as to close the cavity. There was nothing unusual in the operation, the woman is practically in a normal condition and will get well.

DISCUSSION

DR. J. W. IRWIN: I would like to know the relation between the attack of gonorrhœa which occurred seven or eight years before, and the hydrosalpinx. I can hardly see how there might be disease produced by the gonorrhœa to cause pus in the other tube, but why one should take on pus and the other water, is something I would like to have explained.

DR. I. N. BLOOM: I would like to inquire when gonorrhœa was acquired by the woman and how long after that the pyosalpinx developed; also how long before marriage had all gonorrhœal signs ceased in the husband, or had all gonorrhœal signs ceased before marriage. I ask these questions because it is pertinent to the subject discussed at the last meeting of the Surgical Society.

DR. W. H. WATHEN: I do not know how long symptoms of gonorrhœa had been absent in the husband before marriage, but he says that she complained of difficulty in passing urine and had a discharge such as is characteristic of gonorrhœa. I do not know positively that the case is gonorrhœal in origin, though the presumption is that gonorrhœa caused the trouble. A hydrosalpinx is usually a chronic stage of a pyosalpinx, the pus having become sterile and clarified.

DR. I. N. BLOOM: As I have already intimated this subject was discussed before the Surgical Society at its last meeting, and I will give a resume of two rather unusual cases that I reported. One was a man, married, who while on a spree had connection with a prostitute. Four or five days afterwards he sobered up and had coitus with his wife. A day or two after that he noticed a slight discharge from his penis and consulted me. The flow was mucoid, hardly muco-purulent in character, and ceased altogether in four or five days under ordinary treatment. Urination on part of the patient was painless, and there was little or no inflammation around the meatus. He had no intercourse with his wife after first consulting me, and she subsequently developed undoubted gonorrhœa which lasted four or five weeks, which was characterized by the usual symptoms, urethritis, vaginitis and pelvic peritonitis. Previous to the time this man first consulted me he had had no signs of gonorrhœa for ten years.

Another case was the following: A gentleman three years ago had chronic gonorrhœa. The discharge came on at intervals; sometimes it would disappear for a week or two, then become varied in form from a thin, gleety mucous discharge to an occasional purulent flow. Under stimulation by excess in venery, drinking, etc., it would become purulent in character. He also had a syphilitic affection of two or three years standing to the treatment of which he devoted most of his attention, giving himself very little concern about the urethral discharge. Finally he decided to get married, and in July consulted me as to the advisability of this procedure. I told him that so far as syphilis was concerned there was no reason why he should not marry, but so long as there was the slightest discharge from the urethra this feature would debar his union. Proper treatment of this condition was then instituted, and in August I had the flow practically under control, still at times when he had not urinated for three or four hours there was some urethral discharge. The subject of marriage was a serious one, and I took a sample of the secretion to my friend, Dr. Vissman, who made a microscopical examination with the following report—that gonococci were present very few in number, and while perhaps the man could not infect his wife, the possibility was there, and advised against immediate marriage. This was the middle of August; meantime under vigorous treatment by the end of the month all signs of the discharge ceased. The first and last urine throughout September was utterly and absolutely free from any gonorrhœal shreds or threads, and there was no symptoms at all. Early in October about six weeks having passed without a sign of gonorrhœa, I gave it as my opinion that there was very little danger from his marrying. He married, and has never had the slightest discharge from the urethra from that day to this. October, November and a part of December passed. About the middle of December his wife developed a typical case of gonorrhœa with urethritis, vaginitis and pelvic peritonitis involving the left side, having the peculiar pains running down the leg.

The question I brought up to the Surgical Society was a double one: If we admit the specificity of the gonococcus as the causative agent of gonorrhœa, as most authorities have done, and if we admit that the first case I reported had specific gonorrhœa, then we must agree that it was cured in four or five days. If he did not have specific gonorrhœa, how could he have infected his wife with gonorrhœa? If we admit that he did have specific gonorrhœa, and was cured in four or five days, then we must admit something that it is not generally accepted though such things may occur.

In the second case, the grave question was, here is a man who for two months has absolutely no signs of gonorrhœa. Several months before he had such slight signs that I believe physicians as a rule would have permitted him to get married. Yet after having been absolutely free from all symptoms for over two months, married and his wife subsequently developed an undoubted case of gonorrhœa. A distinguished surgeon in discussing the subject recently stated that certain lesions remained for a long time, certainly for a year or more, after apparent recovery from gonorrhœa. The question then comes up when can a man having had gonorrhœa and thinking he is cured, all symptoms being gone, no microscopical signs present—when can such a man marry without danger of infecting his wife? We certainly cannot expect to keep our patients from marrying for a year after the discharge has ceased and after all symptoms have subsided. We cannot say that it is not safe for him to marry for a year. It is a very grave question, especially since a woman once having gotten gonorrhœa is liable to suffer from late forms such as pyosalpinx, hydrosalpinx, etc., etc., as brought out in the case reported to-night. It is a question that ought to be discussed, and I hope some light may be thrown upon it by subsequent speakers.

Dr. L. S. McMurtry: The question Dr. Bloom has presented of course is hardly in line with the discussion of the pathological specimens exhibited yet it brings up a subject that is very extensive. As he has indicated it is certainly a vital question. It has only been in recent years that gonorrhœa in the female has been considered a disease worth paying any particular attention to. It has been only since microscopical researches have demonstrated the characteristic pathogenic germ of Neisser that the fact has been known that latent gonorrhœa in the male can communicate specific disease to the female, and the whole subject as to the time a man can marry after having had gonorrhœa without danger of infecting his wife, etc., is something to be determined by the profession upon recent observations just in line with what is being discussed. I think as yet professional opinion is in a very unsettled state in regard to it. There is no doubt that every man who sees a great deal of the diseases of women will find a large number of young women, who, as soon as they are married, begin to have a very suspicious catarrhal endometritis, oftentimes followed by all the indications of diseased appendages. I have in mind now one case, a young lady who has pelvic inflammation, the appendages fastened down by adhesions, from gonorrhœa contracted during the honeymoon. I know that the husband in this case solicited medical advice as to whether he was in a condition to marry. I do not believe the profession is sufficiently careful in giving advice on this subject; they allow men to run too great risk of inflicting this disease upon their wives. The number of cases of disease of the uterine appendages is very much larger in cities than in the country where people lead a simple rural life; where there is not so much gonorrhœa there are fewer cases of disease of the appendages. There is no question but gonorrhœa is one of the most prolific causes of pyosalpinx. Of course there are a great many cases of pyosalpinx of other origin such as puerperal infection, etc., but gonorrhœa is certainly a very prolific cause. I believe this whole subject should be given more attention by the profession, and some definite and authentic rules formulated concerning the dangers of marriage too early after incomplete cure of gonorrhœa.

In regard to the case described by Dr. Bloom: It is certainly a peculiar one, but it seems to me there is one point that is very clear in the examination made by Dr. Vissman, if any gonococci were found that would have been sufficient evidence that the man was not in condition to marry.

Dr. J. M. Matthews: How do the gynecologists conclude that gonorrhœa of

the gonococcus is the cause of pyosalpinx, etc.

Dr. L. S. McMurtry: That can be demonstrated both by microscopical researches upon the subject and by the clinical facts, just as much by the clinical history as by the microscopical examination. The clinical facts bear out microscopical researches upon the subject almost invariably.

Dr. J. M. Matthews: I want to know why these gentlemen suppose that so many cases of pyosalpinx, etc., result from gonorrhœal infection. I would deny as a surgeon and as a physician that the clinical history or clinical facts would establish it at all. I want to know what is the microscopical investigation upon which they base their opinions.

Dr. L. S. McMurtry: It is the same infection in substance microscopically demonstrated that occurs in relation to the bacillus tuberculosis. Of course there are those who question whether the bacillus tuberculosis is the agent which begets that disease, or is the product of that disease. The same reasoning I think is applicable in the question Dr. Matthews has raised, as to whether the gonococcus is the cause of pyosalpinx as applies in the case of the bacillus tuberculosis being the cause of consumption. I think the two are parallel.

Dr. J. M. Matthews: What I wish to know is this—whether a woman having simply had gonorrhœa and subsequently develops pyosalpinx. Are you willing to say the gonorrhœa is the cause of that condition, or do you rely upon microscopical examination to prove it?

Dr. L. S. McMurtry: Pyosalpinx can be produced by other causes than gonorrhœa but certainly gonorrhœa is one cause, and I will reiterate that the clinical facts will bear it out. I will recite a clinical case: A young man about town has gonorrhœa, is treated by his physician for gonorrhœa; while still having a gleet he marries. Within ten days his wife is in bed with a very ugly leucorrhœa, with tenderness about the uterine appendages. Within six weeks she has fixation of the uterus and the appendages. with what we formerly called pelvic cellulitis which we now denominate pelvic peritonitis;—there are the clinical facts. I will report another case: A woman with the same symptoms and the same condition of the pelvic organs. The family physician says to the specialist that he is treating such a patient presenting certain conditions, and asks what he thinks about the cause. The specialist replies that it may be due to several causes, and inquires as to the probability of gonorrhœal affection. By comparing notes it is developed that the woman's husband at the time is under the specialist's care being treated for gonorrhœa. This is the clinical data which I claim will justify reasoning that gonorrhœa is one cause of pyosalpinx.

Dr. J. W. Irwin: In general practice we often meet with cases such as referred to by Dr McMurtry, and we do not think of calling in a specialist. In going back over a series of years I do not know how many cases such as Dr. McMurtry has described have come under my own observation. They were called then pelvic cellulitis and various other names; I can recall several instances where young men married within a few weeks after the cessation of a gonorrhœal discharge and nothing was ever heard of it; their wives were not affected by the disease; they went on and bore children. I can recall other cases where men who were suffering from gleet, (chronic gonorrhœa) married and they did not infect their wives. And I recall some cases where the husband never had had gonorrhœa, and where the wife had what was called pelvic cellulitis coming on five or six weeks after marriage, in fact where the disease occurred in a severe form it always came on within a comparatively short time after marriage. I believe that gonorrhœal infection may be the occasional cause of pyosalpinx, etc., but I do not think it is at all established as the chief cause, it is the exception and not the rule. The only way the gonorrhœal infection as a cause could be established would be to have the gynecologists—say for one year—to submit all of the pus tubes removed to a microscopist for examination; if the gonococci were found in the tubes, it would be reasonable proof that gonorrhœa had at least a great deal to do with causing pyosalpinx. If the gonococci were absent in the tubes then I should say that the condition was not due to gonorrhœa. I do not know of a better way to reach some definite conclusion. I would suggest that something of this kind be done if it has not already been thought of. I know of many women who have had so-called pelvic cellulitis, peritonitis,

etc., and after suffering a few weeks have gotten well of the disease and subsequently borne children. If their tubes had been infected with gonorrhœa, it is not so reasonable to suppose that these women would have borne children although gonorrhœa does not always cause sterility. It would be well if possible to know just what it is that brings on these conditions of pyosalpinx, etc. My own observation is that a few of the cases may be due to gonorrhœal infection while the great majority are the result of catarrhal causes, septic infection and traumatism.

DR. W. H. WATHEN: In answer to Dr. Irwin's inquiry as to the date of origin of the hydrosalpinx, I would say that it is impossible for anyone to tell, unless the case had been under constant observation. I never saw the woman until two months ago, and the hydrosalpinx was then present. But it has been shown that a hydrosalpinx may be a very chronic affair, and is often a chronic state of pyosalpinx. This is in accordance with the latest pathological investigations. A pus tube may be of very recent origin. There is too little attention given to the inquiries of patients with gonorrhœa as to when they may marry. It is not a question of how long after having had gonorrhœa that a man may marry without endangering the woman to infection, but it is a question of his condition at that time. A man may have gonorrhœa and within two weeks after the discharge had ceased in the acute form, he may marry and never have a recurrence of the trouble and not be able to infect any one, because all the pathogenic germs are destroyed. Again he may be apparently cured of the gonorrhœa, having noticed for a year, or two years if you please, no discharge, but excessive sexual congress usual in married life brings about a constant irritation of the mucous membrane of the urethra in which there are some latent gonorrhœa which multiply and become as virulent as in an acute attack. If these cases were examined into carefully, it would be found that some part of the uretha had not been cured. There would be found a latent gonorrhœa, usually a stricture.

So that instead of the time it should be the condition which should be carefully examined into before any opinion is given as to the advisability of marriage. There is positive evidence that gonorrhœa has produced, and does often produce pyosalpinx. I think we can come to a positive conclusion from the clinical history. Many cases have come under my observation where from the clinical history I was as positive that the pyosalpinx was the result of gonorrhœa, as I ever have been that a patient had gonorrhœa from an examination of the case. The diplococcus of Neisser does not penetrate so deeply into the tissues as does the streptococcus or staphylococcus, and it is more sensitive than either of these, and is often destroyed by contact with other bacteria, or the resisting powers of the system; and for these reasons in pyosalpinx of positive gonorrhœal origin, we often cannot find the gonococcus in a large pus tube by subjecting the pus to a thorough bacteriological examination; in fact in some of these large pus tubes there is no form of pathogenic bacteria. They seem to have by some means become destroyed. But if we will examine into these cases bacteriologically we will find colonies of gonococci in the early stages of gonorrhœal pyosalpinx, but we will not find them if the case is permitted to go on until it becomes old and chronic. We do not know in removing these tubes whether the pus is virulent or not, and just here comes in an important point that ought not to be lost sight of; namely: That every pus tube should be considered virulent for the reason that we cannot from the physical appearance come to any correct conclusion about the degree of virulence. We may have small pus tubes that look simple and harmless, yet they may be swarming with pathogenic bacteria; while large tubes with pus offensive and black may be sterile. The Johns-Hopkins University has done valuable work in this particular by examining specimens as soon as removed. On one side has been found a large pus tube but no bacteria; upon the other side a small pus tube containing only a few drops of pus, with numerous colonies of pathogenic germs.

By some accident one pus tube or pus sac is ruptured in attempts to enucleate it, the intestines and peritoneum are soiled, and the patient makes an uninterrupted recovery. The old idea was that this was entirely due to the resisting powers of the patient. While it may be true that the resisting powers of one patient against infection are greater than another, the in-

fection or exemption from infection, may usually be explained because of the presence or absence of pathogenic germs in the pus or on anything used in an operation. So, as it is impossible from the physical appearance to determine if the germs are pathogenic, we should always if possible, protect the peritoneum from being soiled, and if it is soiled we should in every case cleanse it thoroughly.

Dr. J. M. Mathews read a paper entitled

RECTAL ABSCESS.

(See page 8 REPORTER of July 7th.)

DISCUSSION.

DR. J. W. IRWIN: I rise more particularly to express my commendation of the most excellent paper read by Dr. Mathews. This is certainly a live subject and one of the greatest importance, because nearly every physician meets with such cases. The description given by the essayist is very accurate and to the point.

There is one point in regard to rectal abscess that he did not emphasize, *i. e.* the use of poultices. He mentioned that poultices should not be used after incising rectal abscess; I think we should go further than this, and say that poultices should never be used in the treatment of this condition, either before or after evacuating the abscess.

Dr. W. O. ROBERTS: I think most surgeons of the present day will agree in the main with what Dr. Mathews says in his paper. There is no question but that most of the bad results in cases of ischio-rectal abscess are due to bad treatment. By *bad treatment* I mean just exactly what Dr. Mathews has stated—either allowing the abscess to break, or making an insufficient opening for drainage. I believe that in ischio-rectal abscesses the pus forms within forty-eight or seventy-two hours after the first symptoms develop, and frequently there is a large collection of pus in the cavity when no fluctuation can be discovered by examination from the outside. Like Dr. Mathews, I do not wait for fluctuation to be present before opening the abscess. I also make a large opening, one which will admit with perfect ease the introduction of my finger, and after evacuating the abscess I carry my finger into the cavity to divide any partitions that may be present. I think by this method we will certainly confine the fistula which follows to one tract. The cause of so many fistulæ I believe to be due to the fact that the opening is too small for evacuation of the pus.

My treatment of such cases is about like that advised by Dr. Mathews—a free incision, washing out with mercurial solution, (I prefer that to peroxide of hydrogen,) packing the cavity lightly with iodoform gauze, then applying over the region of the abscess an *abundance* of gauze and over that cotton. I do not think cotton amounts to anything in these cases except as a protection to the gauze. I change the dressing daily until inflammation has subsided, continuing to use iodoform gauze. After inflammation has subsided and the cavity has contracted, I cease using the gauze and employ in its stead a piece of rubber tissue, simply to keep the external wound open until healing takes place behind. I think in the great majority of these cases there is an internal opening, and where this exists I do not believe it will heal until after an operation for the fistula has been performed. Sometimes we have a recurrence of the abscess after a lapse of months, and in these cases recurrence frequently takes place without any apparent cause, such as injury, exposure to cold, etc. I have a case under observation now in which abscess developed a year ago last September. A gentleman otherwise in good health commenced feeling very sore and uncomfortable about the region of the anus, left here to visit his wife who was spending the summer at a seaside resort. Reaching his destination he had a fever, and considerable tenderness about the anal region. He consulted one of the leading surgeons of the East who happened to be at the summer resort at that time, and to my very great surprise exactly the treatment spoken of by Dr. Mathews was carried out, that is poultices, etc., which was kept up for several days; then after the man had had a few chills and sweats, the abscess was opened not by a very large opening, and the man was in a very critical condition for some days. He returned to Louisville about two weeks after the first operation was performed, and I found a considerable boggy condition about the buttocks, the opening being so small that the abscess did not drain thoroughly. I made a free

cut, large enough to introduce my two fingers, and by treating as I have described the abscess cavity gradually closed. I think it was fully a month after he returned before the wound entirely healed and he was considered well. He had no further trouble until two weeks ago when he commenced complaining of soreness about the same region; I saw him in forty-eight hours after the first symptoms developed; there was a boggy condition about the region of the old cicatrix, but no fluctuation. I was satisfied pus existed from the local evidences of inflammation and general fever that he had, so I immediately made a free incision and quite a large quantity of pus escaped. Instead of having an increase of fever following the operation as he did in the first instance, it subsided immediately; he has gone along without an untoward symptom, the abscess cavity has now contracted to a very small fistulous tract and while I have been unable as yet to discover any internal opening, I still believe one exists. My experience with these internal openings is that they are nearly *always* situated just within the anus. I have never met with a case in which the opening was as high up in the bowel as described by Dr. Mathews, though of course they may exist, and have been frequently reported. I do not believe it is a good thing to keep gauze in the abscess after it has contracted down to a very narrow fistulous tract.

DR. J. W. IRWIN: What per cent of the cases bear out the suggestion of Sir Benjamin Brodie, that all such disorders (fistula in ano) are due to a tuberculous diathesis?

DR. W. O. ROBERTS: While we do meet with a great many cases of ischio-rectal abscess resulting from tuberculosis, I think we meet with fully as many due to other causes.

DR. T. P. SATTERWHITE: I believe that a large per cent. of rectal abscesses are due to microscopical openings in the bowel, the juices of the bowel permeating into the cellular tissue causing ulceration. There is one point in connection with Dr. Mathews' paper that I would like him to explain: He said in case of the young lady there was one opening which it became necessary to close, and it had to be very carefully done in order to preserve the sphincter muscle; did he operate upon both sides at once?

DR. J. M. KRIM: This brings up the question as to whether it is advisable to operate upon these cases when there is a tuberculous diathesis. I have seen a few cases of rectal abscess, and remember one Dr. Mathews operated upon who had tubercular trouble, still it gave him immediate relief. However, the patient finally succumbed to tuberculosis.

DR. J. M. MATHEWS: In closing the discussion: To begin with I am very glad that Dr. Irwin sanctions the advice not to use poultices, especially after an opening is made. We all know that poultices in surgery have been relegated to a non-existence. I am glad to know, also, that Dr. Roberts, the eminent surgeon that he is, agrees with me in the main, especially in the treatment of rectal abscesses, as a surgeon he has seen so many of these cases of fistula that have, as stated in my paper, become invalid for life; men and women who are not able to pursue the ordinary avocations of life, the vast majority if not every one due to the bad management of the original abscess by the physician. I cannot agree with Dr. Roberts in one proposition—that the majority of fistulæ in ano, especially those he describes originating in the ischio-rectal fossæ, have an internal opening into the bowel. Such abscesses usully originate from trauma from some outside causes, and that is the very point I tried to make explicit in my paper—that if we could reach the abscess and evacuate it before its ravages were advanced to the point of perforation of the bowel, that we would avoid not only an internal fistula, but any fistula at all. I know that I have operated upon scores of cases of fistulæ that never had an internal opening, that I never penetrated the bowel at all, I have gone into both buttocks and into the fossæ, made large wounds dividing these different cavities such as he speaks of, &c., and cured my patient without ever going into the bowel. Indeed admitting that there might be an internal opening, I believe by such surgery as I have indicated, going down and making a free division using the peroxide solution, or Sol. Bi. Chlor. Hydgr. the inflammatory deposit will be sufficient to close it, if the operation is done in the early stage before any especial pathological changes have taken place.

Dr. Satterwhite states that he believes the majority of fistulæ begin as an ulceration in the rectum which extends into the fossæ or strubture outside. I cannot hold

to that belief, nor do I believe that a heavy percentage of fistulæ have an internal opening at all. It is not necessary for me to state my views about the operation for fistula and the finding of an internal opening; the majority of books say it should be sought for and found before you do an operation. I have differed from these distinguished authorities by saying that when I do an operation I will find the internal opening, that I will never seek for it at all before operating, but in the majority of cases it does not exist.

Dr. Krim asks concerning the propriety of operating upon tuberculous patients who have fistulæ. I wish to say this: That considering the latter day views of this subject, we are constrained to believe that a man may have tuberculous tissue in one portion of the body and not in another. A man may have a tuberculous joint, and yet not have phthitis; he may have tuberculous rectum and yet not have consumption of the lung. Therefore if there is any one thing which is taught plainly to-day in regard to tuberculosis, it is that just so soon as you detect it, that tissue must be removed, because from a small local spot general infection may take place. A man might have a tuberculous condition of a joint, and from that he could have general infection, or phthisis. If a man has a tuberculous ulcer in the rectum, it is the duty of the surgeon as soon as he detects it to curette or cut the whole thing out; therefore in answer to Dr. Krim's question I will say that they demand an operation much quicker than ordinary cases of fistula, much more than ordinary cases of ulceration of the bowel. The moment you decide it is tuberculous you must curette or by other means get rid of that tissue to save the patient from general infection. Now, as Dr. Krim states, here is a case that takes us back to the old doctrine of Brodie spoken of by Dr. Irwin: If a man happens to have consumption (or phthisis) if you please, and should develop fistula, they said it was because he had consumption and therefore they let him go on suffersng the agonizing pain of fistula in ano because they regarded it as an escape or an outlet for this condition of the lung. The case Dr. Krim refers to clearly disproves the old doctrine—we take a man who is suffering from a tuberculous abscess or fistula and we entirely cure him; he gets rid of the rectal trouble, but has general tuberculosis at the time that we operate; he is relieved of the local trouble but after a while dies, because he has consumption. Now the older authorities say that this man died because we did the operation, because we cured the fistula. Therefore I believe if for nothing else, you relieve a man from the local distress he is suffering, and he should be operated upon; certainly if the man has a tuberculous ulcer, fistula, etc., it should be operated on at once and no half measures will do. The same as you would remove a cancerous growth you must remove the tuberculous tissue.

Referring further to the remarks made by Dr. Satterwhite: This young lady as you will understand had both buttocks undermined, they were not little channels, little sinuses, you could run your fingers out into each buttock, there were numerous cavities with bridges across, etc. Her sphincter muscle being the objective point I wanted to preserve it in order to prevent this woman having incontinence of feces. I operated on only one side at a time. I say I had to divide her sphincter muscle on one side; this became necessary owing to the extent of the fistulous tracts. The pathological condition was two years old, consequently I divided the muscle freely on one side, followed up the different sinuses, channels and cavities, allowing the patient to rest three weeks then operated on the other side, opening and curetting freely, but did not go into the bowel. I did not cut into the bowel because I did not find an internal opening; even had there been one I am persuaded that the inflammatory deposits excited by the incision would have been sufficient to close the opening. The one important point was to preserve the sphincter muscle so as not to put this woman in a condition of incontinence of feces. By simply the division of one side, I know she will not have incontinence.

MASTURBATION IN A CHILD (FEMALE) ÆT. 20 MONTHS.

DR. P. F. BARBOUR: A child was brought to see me last summer with the diagnosis of chorea or epilepsy by the family physician. The mother said that the little girl twenty months old had fits. She could not give me a very accruate description of the spells, but the child had one

while at my office so I had the opportunity of seeing just the nature of the attack. She would throw her head back, throw her hands down to her side and become perfectly rigid; eyes wide open and legs extended. She had several such attacks in succescion. I diagnosed the case as masturbation. Upon examination I found that the clitoris was slightly adherent and in a state of irritation. I could not find any irritation about the bowel, pin worms or anything of that kind. The child was put upon bromid of potassium in small doses and improved very rapidly. I lost sight of the case afterward and do not know whether the cure was permanent or not. This is the youngest case of masturbation I have seen.

DISCUSSION.

DR. W. H. WATHEN: How did you come to the conclusion that it was a case of masturbation.

DR. P. F. BARBOUR: I was led to suspect masturbation from the cunning manner and expression of the child. I watched her very closely. The spell was not like epilepsy, chorea or any other form of convulsion. The diagnosis was proven by pressing upon the irritated clitoris when she would have a spell which was a perfect illustration of an orgasm.

MULTILOCULAR CYST OF RIGHT OVARY.

DR. W. O. ROBERTS: Three weeks ago I was called to a distance to see a case of abdominal tumor. The history as furnished by the physician in charge was about as follows: The patient was a lady forty-three years of age, the mother of four children, youngest six years old. Last June she had a menstrual period which was rather more profuse than usual. Since then she had menstruated at irregular intervals and each period was more acant than normal. Early in December she was seen by a physician who told her that she was the subject of an abdominal tumor; the first of January she was seen by another physician who pronounced her pregnant, and a week before I saw the patient he said she had very marked pains resembling labor pains. No membrane had been expelled, but she had suffered with periodical pains, and the doctor thought he detected movement about the abdomen, and said the patient herself and her husband also thought there was some movement. The abdomen rapidly increased in size, and she was tapped by the physician in charge and about a gallon of reddish colored fluid withdrawn, which, however, under the microscopic he said showed no blood cells.

A week afterward the abdomen had refilled and she was again tapped. Four days before I saw her she had been quite flightly; she had some elevation of temperature each day, but the pulse was 88 and of good volume. She was quite anæmic, the abdomen was very large and on examination I made out what I took to be a mulitiocular ovarian tumor. She was irritable, whining a great deal, and seemed to be suffering considerably. I advised a laparotomy and suggested that she be brought to this city. This was on Wednesday. She was brought to the city Thursday and on arrival her temperature was 102 F. The next morning (Friday) it was 101 F., Friday night 100 F., Saturday morning it was still 100 F., pulse 100, and she was still flighty. I did a laparotomy and found an enormous muitiloculas cyst of the right ovary, one of the cysts, the one that had been tapped, was ffiled with black, broken down tissue. The only adhesions were those in the regions where the tapping was done. She rallied from the operation without any trouble, and never afterward developed any abdominal symptoms or any symptoms referable to the operation. But complete aphasia came on the day following the operation. At the end of a week she became paralyzed on the right side and she finally died ten days after the operation in a condition of coma. There was no abdominal distension and no symptom referable to the operation.

Protozoa and Carcinoma.

I. Adler, after critical survey of the literature that has accumulated during the last few years on protozoa and their relations to malignant tumors, concludes as follows: "The existence of parasitic protozoa in cancer is probable, though the greater part of what has hitherto been described as parasitic is certianly not so. No constant nor in any way specific organism has as yet been demonstrated beyond possibilities of a doubt. At present no facts, histological or otherwise, compel the assumption of a parasitic origin of carcinoma, while there are very strong and valid arguments against such assumption."

CURRENT LITERATURE REVIEWED.

IN CHARGE OF ELLISTON J. MORRIS, M. D., AND SAMUEL M. WILSON, M. D.

THE JOURNAL OF CUTANEOUS AND GENITO-URINARY DISEASES

for June, Dr. Henry W. Morton describes three cases of

Raynauds Disease.

This name has been given to a disorder which Raynaud first described in 1862, and called "Local Asphyxia and Symmetrical Gangrene of the Extremities."

In this disorder the extremities appear bluish and then almost black without known cause, and then often perhaps some hours resume their natural color. Ears, nose, fingers, and feet may all be affected unequally. During severe attacks there was indistinctness of vision, and examination showed contractions taking place in the arterioles of the fundus and after awhile forming in another part of the vessel. The uncontracted part was fully dilated, and pulsation in the veins was easily seen. During intervals of the cyanosis the dilatation and pulsation remained. The right eye was less affected than the left and the thumbs were not affected. The color, in the left hand especially, never becomes normal.

By cutting the cervical sympathetic, and electrically stimulating the distal end Raynaud observed the usual vaso-contraction and thought, therefore, that vaso-motor nerve excitement might be the cause of the disorder.

It is probable that all the arteries are contracted in this disorder, but that we notice this only in those whose normal calibre is so small that any lessening of it practically closes them. When owing to syphilis or contracted kidney there is a fibrous thickening of the walls, we can easily see how a vessel, normally so large as to show very little obstruction by contracting, may become almost occluded by slight vasomotor spasm. The question has arisen whether many cases reported to be Raynaud's disease, were not cases of obliteration from organic vascular disease.

Owing to retarded circulation the nutrition of the extremities is interfered with, the finger tips become flattened, the epithelium scales off, the nails become dry and brittle and may split. The color of the finger tips may be white and exposure to cold may increase it. In other cases the bluish color extends to the lips. Pain may or may not be present.

The disease progresses slowly until the arterioles are occluded, and then gangrene, limited to the soft parts, appears. A line of demarcation forms, and the necrosis may involve the hand, or remain limited to a finger tip.

Two cases are given in one of which there was vaso-motor spasm simply. A farmer, forty years old, complained that the terminal phalanges of his hands would become white and continue for hours. This increased so that the condition remained all winter, and finally in summer also. Exacerbation occurred in which the affected parts became almost black. Finally half of the soft parts of the second terminal of the left hand became gangrenous and sloughed off. No explanatory history.

To lessen the excito-motor power Raynaud treated similar cases by the descending current, placing the positive pole on the seventh cervical vertebra and the negative in the lumbar region, and found it beneficial.

THE ARCHIVES OF PEDIATRICS

for June. Dr. J. Lewis Smith writes of

The Alimentation of Young Children.

He thinks ignorance, and neglect of proper care in feeding infants is a great cause of mortality among them.

Sometimes, even among the wealthy, and therefore well-fed, the breast milk is insufficient in quantity and the child is very fretful except when at the breast, then crying and sleepless, losing weight and strength, has scanty urine and stools. Of course this state of affairs is more common in the poor where the mother is insufficiently fed.

Over feeding, causing vomiting, intestinal catarrh and diarrhœa is another common evil to be avoided.

During the first few weeks the new born infant will be applied to the breast from every half hour to every two hours, but after the fourth or sixth week the author says it should be feed every two hours.

Fretfulness, instead of quite sleep, after nursing is a sign that the quantity or quality of the milk was deficient. Mothers who keep late hours and are fond of society may furnish milk apparently all that can be desired, and yet wholly unsuited to the infant. The author mentions a case where a healthy infant applied to the breast of a wet nurse returning from a night's debauch was suddenly seized with fatal convulsions. He thinks artificial food required at six months of age, that a baby should be weaned at ten or twelve months, provided this age does not occur in the hot summer months, and he states also that if an infant be nursed every two hours the milk obtained will be richer and greater in quantity than if four or six hours elapse.

Naming cow's milk as the best substitute for mother's milk for an infant the author mentions some of the objections to its use, prominent among which is the chances of infection from various disease germs getting in the milk after it is drawn from the cow, and of course, the possibility of the cow being unhealthy and perhaps not showing symptons of disease. (*To be continued.*)

Dr. J. W. Ballantyne's article on

Congenital Ichthyosis

is continued. (See Reporter April 28.)

Besides the grave form, there may be described a mild form of fœtal ichthyosis characterized by the presence at birth of a contin-

nous layer of a collodion like substance over the whole body and by a desquamation of this as small flakes like tissue paper. This may be accompanied by ectropion and eclabium, is not usually fatal, and often terminates in cure.

In the recorded cases a family prevalence was noted, and in twenty-six cases where the sex was noted sixteen were boys and ten girls.

In all cases the skin was abnormal at birth but this was only noticed in some cases after the removal of the vernix caseosa.

The coating varied in appearance from a whitish pellicle to that seen where tincture of iodine has been painted on. The lightly stretched waxy appearance is often dwelt on, After a varying length of time fissures appear, usually at first along the lines of the natural folds of the skin, desquamation begins, the exposed skins dries, and in turn desquamates, etc. In a few cases the epidermis becomes horny and resembles adult ichthyosis. As in the grave form, but to a less extent of course, the contracting skin may hold the mouth partly open, making nursing difficult, the nostrils may be choked, and the ears seem glued to the scalp. The eyelids are apt to become ectropic, and the limbs are apt to retain their foetal position.

In some cases the skin becomes normal in a few weeks, or perhaps without being cured, the case permanently improves, but usually the disorder continues through the life of the patient.

In a few sections of skin the microscope showed the affected skin to be only one half the normal thickness, the panniculus adiposus much reduced, and the epidermis thickened to constitute at least one quarter of the total thickness. Probably owing to absence of fat no black layer appeared after application of Flemming's solution. The sweat glands were well developed.

Its differential diagnosis from scleroderma depends on the latter not desquamating, and never appearing in the new-born; psoriasis has not been seen earlier than eight months of age, and is not general. Eczema squamosum is rare in infancy, and the history, distribution, etc., help to distinguish it. Congenital syphilis causes a moist, rather than a dry, desquamation, and other symptoms, and the history will assist in its recognition.

The treatment of ichthyosis has been very unsatisfactory. The chief indications are to support the system by food, nursing, etc., and to soften the epidermis. According to the indications which individual cases presented antimony, mercury, iodide of iron, and cod liver oil, have been used by different men, but internal medication has shown poor results. Inunctions with glycerine, and various fats and oils have appeared to do more good, and Piffard used with some success a solution of peroxide of hydrogen.

Dr. Jerome Walker writes of the

Diet of the Nursing Woman,

(a paper read before the section on pædiatrics in the New York Academy of Medicine.)

The author refers to the growing inability of American mothers to nurse their infants, even when eager to do so; he confesses his inability to account for it, but thinks one reason is the habit of using rich food when the milk appears to be poor. This procedure often increases a dyspepsia which is at the root of the trouble, and the nursling fares worse than before. Sometimes certain foods produce digestive disorders in the mother, sometimes only the child shows the effects, and in a third class neither mother ner child seems injured by anything taken.

The food that seems most generally to meet all requirements is cow's milk, easily digested. Digestion is sometimes assisted by warming the milk, mixing one fifth or one sixth of its bulk of lime water with it, or, especially at night, adding a teaspoonful or two of essence of ginger. A general mixed diet is necessary usually, and to assist in its ready digestion it is well to use one of the malt extracts. The use of malt liquors tends to increase the quantity of milk at the expense of its quality. Occasionally it is necessary to add some one of the many prepared foods.

Poor hygiene, deficient out door exercise, nervous excitement, constipation, etc., all have a prominent part, and often a trip to the seashore seems the most useful remedy to be had.

Other papers in this issue are "Surgical Treatment of Idiocy and Microcephalus," by Dr. A Jacobi; "Pus Inoculations and Certain Eye Affections in Children," by Dr. George Carpenter; " Hæmatoma of the Sterno-Mastoid Muscle," reported by Dr. Floyd M. Crandall; "Removal of the Head of the Femur for Tubercular Disease," by Dr. B. Merrill Ricketts; "Pemphigus Vulgaris Acuta in a Child," by Dr. Henry E. Tuley, and some clinical memoranda.

Thyroid Extract in Washerwoman's Eczema, and as a Local Application.

S. H., aged 42, a washerwoman, was placed on the sick list on January 27th. The patient was suffering from an acute attack of typical eczema, of the impetiginous type, with intolerable itching and exudation. The legs and arms were chiefly affected. She was unable to stand to do her daily work. She was treated with the ordinary remedies for a week, and these failing to do her any good, I determined to give thyroid tabloids a trial.

On February 6th three tabloids were daily prescribed. The result was most gratifying. In twenty-four hours she began to peel, and when I visited her on February 9th the epidermic scales and crusts filled the bed and littered the floor. The patient expressed herself much improved by the medicine, and the soreness about her limbs had disappeared. The eruption still further yielded to treatment, and on February 12th she was able to attend at the out-patient department practically convalescent.

This patient occupied a small room in a back court, the general surroundings being very unfavorable for a good recovery. I think the remedy undoubtedly had a curative effect in this case.

PERISCOPE.

IN CHARGE OF WM. E. PARKE, A.M., M. D.

MEDICINE.

Absorption of Salicylic Acid by the Skin and its Use in Acute Rheumatism.

Dr. Bourget (*Revista de Ciencias Medicas de Barcelona,*) concludes as follows:

1. Absorption of salicylic acid by the skin is very rapid and intense. The skin of youthful individuals is most absorbent, while persons with white skins are more so than those with brown or black.

2. The rapidity and intensity of absorption depends upon the vehicle in which the acid is dissolved. Fatty substances especially favour its introduction through the skin, while with vaseline or glycerine it is less.

3. The treatment of acute articular rheumatism by a salve of salicylic acid and turpentine is to be recommended. It is less servicable in other forms of rheumatism, yet it might be of use as an adjunct in massage.

4. In gonorrheal rheumatism it is inactive.

Diphtheria.

The Polyclinic summarizes the treatment as follows:

1 Germicidal treatment, preferable by the use of strong hydrochloric acid, used early to be effectual; especially valuable in cases begining on the tonsils.

2. Local cleanliness by the use of a weak antiseptic solution in the pharynx.

3. Nasal syringing with the same solutions in every case where there is nasal discharge.

4. Alcoholic stimulents begun as soon as the first systemic effects of the poison are seen, and in very severe cases pushed to the point of tolerance.

5. Calomel fumigations as soon as laryngeal symptons appear.

6. Intubation in laryngeal cases not relieved by fumigation.—L. Emmett Holt in *Archives of Pediatrics.*

Jaundice and Emotional Disturbance.

Dr. E. Lubbock (Fulham Road, S. W.) writes:

"On the evening of March 31st last I delivered a fragile, highly sensitive young lady (by no means hysterical, by the way), a primipara, of a still born male child. The 'waters,' I was informed had broken and escaped ten days previously. Delivery was instrumental, and was accomplished, while the patient was under chloroform, with some difficulty. Some thirty-six hours after, my patient, otherwise doing well, developed jaundice, which speedily became intense. There was no pain, no nausea. and the temperature was normal. The lochia were foul, otherwise there have been no troubles, and to-day, five days since its appearance, the jaundice is beginning to fade. Four of my medical neighbours whom I have asked have never seen a like case, neither has such a one been seen by my old teacher, a gentleman who has been for many years obstetric physician to one of the great London hospitals, so I venture to bring the case to your notice. Was the jaundice due to emotional disturbance?—*British Medical Journal.*

The Physical Diagnosis of Gall Stones.

Gebhardt observes that the attack usually begins four or five hours after the chief meal, that is, shortly after the entrance of the stomach contents into the duodenum. According to the size and position of the stone after it has passed into the common bile duct, distension of the gall-bladder may be recognized at once, or later (when the gall-bladder has been copiously filled, or not at all.) The swelling lies between the right parasternal line and the anterior axillary line, mostly a little to one side of the right rectus muscle. If the gall-bladder is much distended it may give rise to errors in diagnosis. This distention only takes place in a minority of the cases. It may be absent owing to the smallness of the gall-bladder, or to the obstruction being incomplete, or lasting too short a time. It occurs in severe attacks, or in those who have had repeated attacks. The commencement of the attack may last a couple of hours without pain, during which time the gall-bladder may be palpable. The shrinking of the swelling shows the end of the attack.

This is due to local peritonitis, and it explains the continuance of pain. An ice-bag is more useful here than warm applications. The liver may swell after severe attacks and fever be present. Attacks may occur with pain and fever, but there is neither swelling of the gall-bladder nor of the liver, and no stone is found in the stools. It is thought that the stone slips back into the gall-bladder, but other possibilities exist. The swelling of the gall-bladder may be due to obstructions having other causes, but it does not occur in cardialgia, nor in heptic colic of purely nervous origin. This latter is observed in tabes, hysteria, multiple sclerosis, and may even be accompanied by jaundice. When, after several attacks no stone is found, no friction sound heard, and no swelling of the gall-bladder felt, cholelithiasis may, with tolerable certainty, be excluded, and neurotic hepatic colic may be assumed with great probability.—*British Medical Journal.*

Extract of Bone-Marrow in the Treatment of Anæmin.

Mann (*Lancet*, No. 3680, p. 599), viewing the red matter of bone as the chief agent in promoting the development of red blood corpusoles, concluded that an extract of this substance, introduced into the human organism

while in an anæmic state, might act as a stimulant to the formative process, and increase the rate of production of the red corpuscles. As the tissue-forming power is more active in young than in older animals, the bones of the former are to be preferred as a source of the extract. To prepare this the heads of the long bones obtained from recently killed calves, with other portions of bone that contain red marrow, are broken into small pieces and digested in glycerin, with frequent agitation. The extraction is complete after the lapse of several days, when the extract is filtered off and is ready for use. It is red or reddish-brown in color and devoid of unpleasant taste or odor. It may be given in teaspoonful doses once or twice daily. In a series of cases of anæmia of varying kind and origin, in which the extract was employed, encouraging results were obtaned.—*Med. News.*

Tracheal Irrigations in the Treatment of Croup.

After giving the details of a successfully treated case of croup by the method of tracheal irrigations, the child being placed in an inclined position, Guelpa (*Journ. de Medicine de Paris*) draws the following conclusions. (1) Tracheal irrigations, while the child lies with the head lower than the feet, are not only destitute of danger, but are also well borne and easy of application. (In the case described by the author the irrigations were practiced by the father of the little patient, with the aid of the servant.) (2) The constant inclined position of the patient in bed facilitates the expulsion of bronchial mucosites and is a very practical measure, of great value in the treatment of croup in all the stages of the disease. (3) Abundant irrigations exercise a beneficial influence also in diphtheritic manifestation of the throat and nose; therefore they ought likewise to be practiced in cases of diphtheria of the larynx and trachea. (4) Finally, the case that has been described seems to show that, with reference to the etiology and treatment of concomitant or late thoracic lesions of croup, these cannot be looked upon as direct or indirect consequences of respiratory infection, but that the condition of the digestive organs must be considered also; indeed, the case shows that the infection of the bronchi and pleura was of an intestinal origin.—*Therapeutic Gazette.*

SURGERY.

In-Growing Toe Nails.

Much is continually being written and published in reference to this common and troublesome affection, caused by high heeled and narrow toed boots and shoes. The following treatment is about all that can be said philosophically in regard to the treatment. Cut out a triangular portion of the center of the nail, having a wide base at the free edge of the nail, and a fine point at or near the matrix. This will cause the nail to contract from the edge toward the center, and if kept up for six months will quite alter the shape of the nail making it filbert-shaped and prominent in the center. The edges of the nail should be raised and separated from the soft parts into which they intrude with a piece of worsted, coated with mercurial ointment, or Monsel's solution of iron.

When very sensitive granulations exist, some extract of belladonna and resin ointment rubbed together form a good application.

Syphilis of the Spinal Cord.

Virchow (*Med. Week*) is of opinion that evidence is lacking of ætiological relationship between syphilis and tabes, nor is it possible, clinically speaking, to decide the question from the information furnished by the "reminders," seeing that syphilis is practically of universal distribution. Moreover, there is nothing in the evolution of tabes that can be compared with what is known as visceral syphilis, which tabes would most likely resemble if it were in any way dependent on such a cause. But tabetic patients present no symptoms of visceral syphilis, nor is any tabetic lesion observable in grave cases of visceral syphilis. This is no absolute demonstration of the non-existence of the relationship which is said to exit between syphilis and tabes. The evidence in the favor of the latter hypothesis is strong enough, in his opinion, to induce him to suspend judgment on this much debated question. This position is essentially the judical one adopted by many neurologists not only as to tabes but also as to paretic dementia.

Nerve Suturing.

When drugs fail, surgery often comes in and effects a cure. The fact that severed and even exsected nerves will unite when such a thing is not desired and also that ends of nerves at times will not unite even after the most careful suturing, has led Dr. DeForest Willard to perform some experiments on animals in nerve suturing. He operated on dogs and after suturing the nerve ends he let the animal live until the function of the nerve was restored and then made a post-mortem on the killed animal and examined the sutured part of the wound both macroscopically and microscopically and from his work published in the *International Medical Magazine* he thinks he has demonstrated that:

1. Functional restoration is possible.
2. The closer the apposition the more speedy and complete will be the restoration.
3. Union is accomplished chiefly by the reaching out and development of nerve-fibres from the divided proximal end, these fibres pushing their way across the connecting link of fibrous tissues.
4. Engrafted nerve-tissue or flaps cut from the nerve may serve as a framework for new tissue, or may produce embryonic nerve-fibers capable of assisting in reunion.—*Maryland Med. Journal.*

OBSTETRICS.

Pregnancy after Ventrifixation.

Lohlein (*Deut. med. Woch.*,) says that ventrifixation has maintained its position as a method for maintaining the uterus in a forward position with moderate elevation which, is at once reliable and unattended by unpleasant consequence. It is, however, indicated only when very considerable inconveniences are to be attributed to the abnormal position of the uterus. He reports two cases in which pregnancy occurred after ventrifixation: (1) A woman, aged 30, had ventrifixation performed in July, 1892, on account of prolapse; in December, 1893, she was delivered of a child; the involution of the uterus proceeded satisfactorily. (2) A woman, aged 35, had myomectomy performed in November, 1892; as the uterus was retroflexed, the bed of the tumor was stitched to the abdominal wall; five months later she had severe nausea and vomiting, and was found to be pregnant; the adhesions between the uterus and abdominal wall could be felt; subsequently she was delivered of a well developed child, which, however, died shortly afterwards. The ventrifixation was undertaken here to guard against bleeding and the infection of the peritoneum, in addition to the above named reason. This method has been of service to the author in cases of the enucleation of large myomata He cites a case in which a rapid pulse and raised temperature led him to reopen the adomen, and he stitched the bed of the tumor to the abdominal wall with the best results. The indications for ventrifixation are thus not to be limited by any fears in regard to conception and gestation. The bands of adhesions take part in the involution just as the utero-sacral and broad ligaments do. Thus there is reason to believe that the fixation will still remain sufficient. In both cases there was marked nausea and vomiting during the early months of the pregnancy, severer than in previous pregnancies.—*British Medical Journal.*

ARMY AND NAVY.

CHANGES IN THE U. S. MARINE HOSPITAL SERVICE, FOR THE FOUR WEEKS ENDING JUNE 23d, 1894.

Hermon A. H., Past Assistant Surgeon, granted leave of absence for five days, June 18th, 1894.

Woodward R. M., Past Assistant Surgeon, to proceed to Cleveland, Ohio, for duty, June 11th, 1894.

Wertenbaker C. P., Past Assistant Surgeon, to proceed to Reedy Island Quarantine, for special temporary duty, June 12th, 1894.

Steward W. J. S., Assistant Surgeon, granted leave of absence for thirteen days, May 29th, 1894.

Prochazka Emil, Assistant Surgeon, to proceed to New York, N. Y., for duty, June, 11th, 1894.

Thomas A. R., Assistant Surgeon, to proceed to St. Louis, Mo., for duty.

NEWS AND MISCELLANY.

DEER PARK

ON THE CREST OF THE ALLEGHENIES.

To those contemplating a trip to the mountains in search of health and pleasure, Deer Park on the crest of the Allegheny Mountains, 3,000 feet above the sea level, offers such varied attractions as a delightful atmosphere during both day and night, pure water, smooth, winding roads through the mountains and valleys, and the most picturesque scenery in the Allegheny range. The hotel is equipped with all adjuncts conducive to the entertainment, pleasure and comfort of its guests.

The surrounding grounds, as well as the hotel, are lighted with electricity. Six miles distant on the same mountain summit is Oakland, the twin resort of Deer Park, and equally as well eduipped for the entertainment and accommodations of its patrons. Both hotels are upon the main line of the Baltimore and Ohio Railroad, have the advantages of its splendid Vestibuled Limited Express trains between the East and West. Season excursion tickets, good for return passage until Octobor 31st, will be placed on sale at greatly reduced rates at all principal ticket offices throughout the country. One way tickets reading from St Louis, Louisville, Cincinnati, Columbus, Chicago, and any point on the B. & O. system to Washington, Baltimore, Philadelphia or New York, or vice verse, are good to stop off at either Deer Park, Mountain Lake Park or Oakland, and the time limit will be extended by agents at either resort upon application, to cover the period of the holders visit.

The season at these popular resorts commences June 23d.

For full information as to hotel rates, rooms, etc., address George D. DeShields, Manager, Deer Park, or Oakland, Garrett County, Maryland.

SUMMER VACATION TOURS.

The Baltimore and Ohio R. R. Co. now has on sale at all its offices east of the Ohio River a full line of tourist excursion tickets to all the lake, mountain and seashore resorts in the Eastern and Northern States and in Canada. These tickets are valid for return journey until October 31st. Before deciding upon your summer outing it would be well to consult the B. & O. Book of "Routes and Rates for Summer Tours." All B. & O. Ticket Agents at principal points have them, and they will be sent post paid upon receipt of ten cents, by Chas. O. Scull, General Pass. Agent, B. & O. R. R., Balto., Md.

THE

MEDICAL AND SURGICAL REPORTER.

No. 1951. PHILADELPHIA, JULY 21, 1894. VOL. LXXI—No. 29

ORIGINAL ARTICLES.

THE RELATION OF CHEMISTRY TO MEDICINE.

OSWALD L. SCHREINER, PH. G., BALTIMORE, MD.

It would be pure, inexcusable ingratitude upon the physician's part to ignore the assistance of chemistry in his professional career. Chemistry has without a doubt done more to further the art and science of medicine, than all the other allied sister sciences. The progress of the healing art is in direct proportion to the advance in chemistry; daily this fact is verified by the articles mentioned in the prescription of the physician. He no longer (or very seldom, at least,) orders a long list of crude drugs to be comminuted, and an infusion or decoction to be prepared, as was the custom not so very long ago; but he now orders mostly the active constituent, be it alkaloid, glucoside, volatile oil, resin, or oleoresin, of the drug, combined with definite inorganic compounds, or even with one or more of the newer synthetic remedies, whose number has increased so remarkably within the last decade. Are all these not directly or indirectly the product of chemical science? Had not their discovery or manufacture a bearing upon chemistry? Was not in their production chemical force or affinity called into action? Or is not chemical action going on in the animal system at all times, and when these remedies are administered, is not chemical reaction taking place between them and the constituents of the individual cells? Let us then consider this subject in historical order.

Many of the inorganic compounds were known to the ancients, but were not very extensively used in medicine; vegetable and animal drugs were the remedies then in vogue. It would be useless to mention the many curious and ridiculous animal remedies of the past; they have been mentioned so often. After a time chemical facts became more and more known through the untiring alchemist, then in search of the method or process by which the baser metals could be changed to gold, and always on the look-out for the "elixir of life," by means of which the old, feeble and unhealthy might be changed to eternal youth and health. As he, never abating, never lacking energy to discover these impossibilities, formed a new compound, his first duty was to ascertain how much nearer he was to his great object. Finding that his compound was not gold, contained no gold, and no gold could come of it, he would try it upon the animal system, to ascertain its action thereon. Thus the physiological properties of these compounds were being ascertained and put to practical use in combating disease. The barbaric remedies were fast losing ground. The *art* of chemistry still advanced, more facts were continually added to the list; but it remained for Lavoissier, the "father of the science of chemistry," and Dalton to discover the relation existing between these facts and chemistry became a *science*.

By this chemistry received a new impetus, the newly created science prospered, and medicine had gained a valuable ally. Physiological chemistry grew and

prospered from the mother science. Much has been achieved by this branch and doubtless more will be done; the field is broad, the work is interesting, and much remains to be known. The results achieved by this branch will not be reviewed here, they are known to all. We call physiological chemistry a branch. Yet is it a branch of chemistry or of medicine. The point is hard to decide.

By this time the barbaric remedies had almost entirely disappeared; vegetable drugs and inorganic compounds had replaced them. With the aid of chemistry, man now sought out the active parts of such important drugs as opium, cinchona, etc. Since the time of the discovery of morphine by Sertürner, medicine has continually been enriched with active medicinal agents. Still their number is increasing, still they come, the end is not yet. To-day the active constituents of almost every drug are known; many of these have been applied advantageously in the treatment of disease. Not only do these substances exist as a concentrated part of the drug from which they are obtained, but they have been investigated by the chemist and found to be definite chemical compounds, that is they never vary in their composition. They have been classified into groups. For instance, the volatile oils, the mixed oils, the alkaloids, the resins, the glucosides, etc. all fall into groups, the members of which show allied chemical constitution and properties. The constitution of these compounds—that is, the relation which the atoms or groups of atoms bear to each other in the molecule of the compound—has and is yet being investigated. Many are already known, and their constitution being known, they can be prepared synthetically by the chemist, by means of a series of chemical changes. During the investigation of these compounds the chemist formed many derivatives of them, some of which have become valuable therapeutic agents, such as apomorphine obtained from morphine or apocodeine from the allied alkaloid codeine.

In the attempt to form the alkaloids synthetically many new intermediate products are being discovered, whose physiological action is then ascertained by experiments upon the lower animals. In this manner many of the valuable "coal tar derivatives" have been obtained. The physician can assuage pain and reduce dangerous fever by means of the antipyretic, analgine and hypnotic remedies in cases against which his forefathers were completely powerless. In the course of manufacture and investigation of the aniline colors many of these compounds are formed. Our most valuable remedies of to-day were discovered in this or similar manner; salicylic acid, salol, phenacetine antipyrine, acetanilid, sulphonal, trional, tetronal, etc.

In 1869 Mendelejeff gave to chemistry its most important, the fundamental law of chemistry, the *periodic law*. It may be briefly stated as, "the properties of an element are functions of its atomic weight." Since the announcement of this law it has not only been proven that physical and chemical properties are functions of the atomic weight, but also that the action upon the animal system bears a relation to the atomic weight. The physiological action of the elements in reference to the periodic system has been investigated by Dr. Curci of Italy. The results obtained by this investigator may be briefly stated. If we take the elements of group I of the periodic system, we will find that those with the lower atomic weight act mostly upon the muscles, while those with higher atomicity act strongly upon the nervous system. They may be arranged as follows:

Act on the muscles.
Cs, Rb, K,—Li—Na—Cu, Ag, Au.
Act on the nerves

Lithium and sodium connect cæsium, rubidium, and potassium, on the one side, with the copper, silver and gold on the other. The elements of group II may be similarly arranged.

Act on the muscles.
Ba, Sr, Ca,—Be—Mg—Zn, Cd, Hg.
Act on the nerves.

The other groups may be taken up in like manner. Thus we see that those elements which are most closely related to each other in chemical properties, also resemble each other remarkably in their action upon the animal system.

Analogy or identity in chemical composition, however, is not a guarantee of similar physiological action. Ammonium cyanate and urea, or acetic acid and methyl formate contain the same elements in the same proportion and quantity, that

is, they have the same identical chemical composition, yet their physiological properties differ, due to a different atomic arrangement. Thus,

Ammonium cyanate. Urea

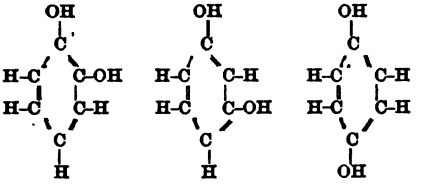
$NH_4 \diagdown CN \diagup O$ $NH_2 \diagdown NH_2 \diagup CO$

Acetic acid Methyl formate

$C_2H_3O \diagdown H \diagup O$ $CHO \diagdown CH_3 \diagup O$

Physiological action is therefore dependent upon the arrangement of the atoms within the molecule of the substance. Further, we may also say that physiological action is at least modified, if not changed completely, according to the relation the groups of atoms or radicals bear to each other in the compound. Pyrocatechin, resorcin and hydroquinone are in chemical constitution closely allied, differing only in the relative position of the two hydroxyl groups (OH) contained in the molecule. This difference may be noticed by comparing their constitutional formulas here given.

Pyrocatechin Resorcin Hydroquinone



In pyrocatechin the two hydroxyl radicals (OH) are represented as adjoining each other (ortho-position), in resorcin they are alternate (meta-position), and in hydroquinone opposite to each other (para-position). While the physiological properties of these compounds are similar they are not wholly identical. Again, in the manufacture of that excellent remedial agent, phenacetine, only para-phenetidin is used; before being acetylized it is carefully separated from the ortho-phenetidin which accompanies it. Exactly why these differences in property should be so, we do not know.

Further, the substitution of one radical for another in a compound will increase or diminish its therapeutic value. As illustration of this we may take sulphonal and the allied compounds, trional and tetronal. Trional is sulphonal in which one of the two methyl groups (CH_3) has been replaced by an ethyl group (C_2H_5); while in tetronal two ethyl radicals have replaced the methyl groups in sulphonal. In other words, sulphonal contains two methyl radicals, trional one ethyl and one methyl radical, and tetronal two ethyl radicals, otherwise the compounds are identical. Their relationship will be readily seen by a comparison of formulas.

Sulphonal Trional Tetronal

$C\begin{cases} SO_2C_2H_5 \\ SO_2C_2H_5 \\ CH_3 \\ CH_3 \end{cases}$ $C\begin{cases} SO_2C_2H_5 \\ SO_2C_2H_5 \\ CH_3 \\ C_2H_5 \end{cases}$ $C\begin{cases} SO_2C_2H_5 \\ SO_2C_2H_5 \\ C_2H_5 \\ C_2H_5 \end{cases}$

Tetronal is, according to Baumann and Kast, twice as powerful as sulphonal; trional occupying an intermediate position in therapeutical effect as well as in chemical constitution.

We will now consider a most important part, namely the modification of compounds by the chemist to meet the requirements of the therapeutist. We will select as an illustrative case the recently introduced antipyretic "phenocoll," a derivative of phenacetine. The only objection to the excellent phenacetine is its almost entire insolubility in water. Its innocuousness is believed to be due to the presence of the oxyethyl group; a group not present in antipyrin nor acetanilid, hence their toxicity. For instance, benzocoll, which differs from the innocuous phenocoll only in *not* containing the oxyethyl group, possesses the toxic properties of acetanilid. The problem then as placed before the chemist by the therapeutist, was to render the insoluble phenacetine soluble, without affecting the oxyethyl group, and without destroying its antipyretic property. The numerous soluble compounds which were produced, were all found to be devoid of antipyretic properties. The introduction of a salt forming amido group into the acetyl residue of the original acetyl-amido group was then tried. The product, amido-acetyl-phenetidin or "phenocoll," retains the innocuousness and prompt antipyretic action of phenacetine, while it is, when in combination with acids as salts, very soluble. It is claimed to be more prompt in action than the latter substtanc, one to its greater solubility and consequent more rapid absorbtion. Here we see chemistry lending a helping hand to therapy, not only in producing new substances which may be used in its do-

main, but also modifying such substances to meet certain requirements of disease.

In glancing over this field of research the question presents itself to the inquiring mind: What wonderful remedies may not the future have in store for us? What may not the future chemist and physiologist bring to light? Can the mind conceive the day when these relations between chemical properties and constitution and physiological action will be known; when physiological properties may be predicated with certainty of a compound which does not as yet exist, but whose chemical composition and constitution is known. When the periodic system was first formed, there were found gaps in the series of elements. Mendelejeff claimed that elements would yet be found which would fill these vacancies; and by means of his admirable law he described the properties of these elements and stated their atomic weight and valence, years before they were discovered. Three of the elements have since been discovered and found to possess the properties assigned to them.

Chemico-physiologic research is in the proper channel; it may be likened to a river, continually gaining volume, force and extent as it rolls onward to its destination—the health, happiness and welfare of the human race.

PLACENTA PREVIA CENTRALIS: REPORT OF A CASE—TREATMENT, ETC.*

J. CAMPBELL EDIN, M.D., C. M. (McGILL,) L. R. C. P., SEAFORTH, ONT.

I was called on the 16th of April last at 11 p. m. to see Mrs. B., of Seaforth, who was over eight months advanced in her eighth pregnancy.

She was not in labor, but was alarmed on account of a sudden hemorrhage which had taken place without pain. Upon enquiry ascertained that a similar flow of blood had taken place under the same conditions about the middle of February, and again about the same time in March, but she had not called in a physician. The discharge, however, upon this occasion was more profuse than upon either of the previous occasions.

Made a digital examination and found the internal os covered by a soft spongy substance. By pressing the uterus firmly down, could feel a hard body above the spongy mass in question.

The cervix was rigid and undilatable. The examination caused some pain with a slight increase of the discharge. My diagnosis was placenta previa centralis. Told the patient and her friends that she was not going to be confined that night. With the idea of relaxing the parts and producing rest—gave her gr. xvi of chloral hydrate and repeated with gr. viii every half hour until she was asleep, which was within the hour when I left her for the night.

From this time we kept a close watch upon our patient, keeping her under the influence of the chloral—with an occasional dose of morphia, so as to keep down all pain and procure sleep at night.

There was a moderate flow of blood nearly all the time—but not enough to weaken her to any appreciable extent. Examinations from time to time satisfied me that the parts were being prepared for the trying ordeal through which she must sooner or later pass.

On the morning of the 21st, while on my way to the patient's house, met a messenger coming for me with a note which stated that she had flooded more profusely than ever before.

When I reached the house and saw the amount of blood passed and examined the patient—I made up my mind that the time for action had arrived.

Asked for a consultation with another physician when the assistance of my townsmen, Dr. Smith was procured.

A careful digital examination revealed the lower surface of the placenta, which could be felt through the cervix, its rough spongy texture rendering mistake almost impossible. It was a clear corroboration of my previous diagnosis. The index finger could be passed beyond the free edge of the placenta on the right side of the patient, and high up could be felt the vertex presentation in the second position.

*Read at the meeting of the Ontario Medical Association held in Toronto, June 6th and 7th, 1894.

There was every evidence that the unavoidable hemorrhage was due to the placental separation as a consequence of cervical dilatation.

The gradual loss of blood as previously related, which had been going on for some days, with the fact that there was no doubt as to the actual condition with which we had to deal, called for immediate treatment, to save if possible both mother and child.

In regard to the latter, however, palpation and oscultation gave little hope to expect the delivery of a living child.

Upon consultation it was decided to put the patient under chloroform — dilate with the hand—turn by the bi-polar method (if possible,) and deliver without any more delay than would be absolutely necessary—using the forceps for the delivery of the head, if required.

The consent of the patient and her husband having been obtained, she was carefully prepared for treatment as follows: The lower limbs, from waist down, were sponged with hot bi-chloride solution—care being taken to thoroughly cleanse the vulva and surrounding parts.

The vagina was carefully irrigated with a hot carbolic solution 1 to 40, from a fountain syringe and the patient placed upon a perfectly clean compress of folded sheets. After a careful use of the nail brush on my hands and arms and washing my hands for several minutes in hot carbolized water, and afterwards immersing them in a 1 to 2,000 solution bi-chloride of mercury, I felt that nothing had been neglected to render everything in contact with the patient thoroughly aseptic.

We have thus minutely described the preparation of the patient, as we positively believe that her excellent recovery depended in a great measure on the antiseptic precautions used.

As soon as my assistant had got the patient under the influence of the chloroform I lubricated the back of my right hand with boric acid ointment and proceeded to pass it into the vagina. After this I began dilating the os and cervix which we found tolerably dilatable, using first one finger, then two, next three, and lastly the whole hand.

I passed the hand up the right side where the placenta was partially detached until I reached the bag of waters, and by pressing down the uterus with the left hand was able to rupture them. I could distinctly touch the head of the child, and by internal and external manipulations was able to turn by what is known as the bi-polar method—and got hold of a foot which I brought well down—and all hemorrhage ceased.

I describe this the more particularly as most authors omit any description of the operation, and others who describe it never performed it themselves and either speak too lightly of it or surround it with unnecessary warnings which are apt to frighten rather than aid the inexperienced operator.

Pains now came on at regular intervals and we used traction during each pain. We had some difficulty in getting the arms down as they were extended over the head of the child. We succeeded and the head engaged in the superior strait. The real difficulty now began. I found that with all my art and as much force as was justifiable I could not deliver the head. Upon particular examination I made up my mind that we had a hydrocephalic head to deal with, which diagnosis was afterwards proved to be correct We now had recourse to the forceps, which was in readiness for such an emergency. I managed to apply them without much difficulty and directing the doctor to press firmly on the uterus, made traction during the pains and soon had the head in the world. The placenta followed shortly afterwards, its expulsion being aided by Crede's method.

No ergot was given owing to the nausea occasioned by the chloroform. The whole operation as described occupied only about thirty-five minutes. After allowing the patient to rest for a few minutes, the clothing was carefully changed and the external parts and limbs sponged carefully with the antiseptic solution. The bandage and compress over the uterus were then applied and over the vulva was placed an antiseptic pad.

Severe after pains which followed were relieved by hypodermic injections of morphia.

The after treatment consisted in syringing the vagina night and morning with hot carbolic acid lotion and in giving a mixture of magnes. sulph., which produced on an average three loose motions daily, and most effectually prevented any trouble from the secretion of milk.

The temperature never rose even one degree; she made an uninterrupted recovery.

Remarks:—There is no complication in pregnancy more trying to the physician than placenta previa, and by trusting to the old method of plugging and waiting, the case drags slowly, a constant source of danger to the patient and anxiety to her attendants.

By the new method—namely, the induction of premature labor—under antiseptic precautions and the disuse of the tampon as a means of controlling hemorrhage, we avoid the danger of septicemia on the one hand and fatal hemorrhage on the other. Moreover it can be shown that the chances of life to both mother and and child, but especially to the mother, are much improved by the new method.

Dr. Simpson, of Edinburgh, who compiled a table of 399 cases, shows that 115 of the mothers died, or 1 in 3. Muller reckons that the death rate to mothers by the older methods was 36 to 40 per cent.

By prompt induction of labor, Thomas had two deaths in 11 cases. Hecker had 3 in 40 cases. Hoffman 2 in 30 cases, and Murphy 15 cases without a single death.

By the use of the plug—no matter how aseptic it is made, the cervix with its bleeding vessels is exposed to the air, with its poisonous germs—the very condition that makes compound fractures so much more serious than simple ones.

By the method we advocate, this danger is avoided.

Conclusions:—In conclusion then we contend that in the treatment of placenta previa the following rules should be followed:

1st. Terminate gestation as soon as possible.

2nd. Control the hemorrhage by the introduction of the hand into the vagina—the index finger through the cervix, and separate the placental attachment as far as possible.

3rd. Discard the tampon as a fruitful source of infection.

4th. Use the hand in dilating the cervix after the manner we have just described—turning by the bi-polar method—if possible.

5th. Take aseptic precautions previous to the operation and carry out the most approved antiseptic treatment afterwards.

A NEW OPERATION FOR PILES.

J. S. WIGHT, M. D., Brooklyn, N. Y.*

The instruments required are: a pair of tenaculum forceps; a strong curved needle; a pair of pressure forceps, with slightly curved jaws that are about four centimetres in length; and a pair of scissors curved on the flat.

The pile is gently drawn down with the tenaculum forceps, and then clamped with the pressure forceps. All that part of the pile below and outside the pressure forceps is cut off evenly with the scissors; a knife may besubstituted for the scissors. The needle is armed with a cat-gut suture of proper strength; and the suture is carried around and above the jaws of the pressure forceps, so as to embrace and include all the stump of the cut-off pile; that is, the suture is a continuous one. One end of the suture projects from one border of the pile stump, and the other end projects from the other border. The ends of the suture are now put together in the first step of the surgeon's knot. Then the pressure forceps are unlocked and gently removed, being extracted from the loops of the continuous suture, which is at once drawn tight and the tying completed. If these movements are well executed, there will be no hemorrhage, the wound made by the excision of the pile being securely closed. Each pile, in its turn, is dealt with in the same manner, the pressure forceps being applied in such direction as the judgement of the operator may dictate.

This method of operating has the following advantages: (1) Easy and rapid work; (2) Absence of hemorrhage; (3) Complete excision of the piles; (4) The suture-ligatures take care of themselves; (5) Repair with a small quantity of scar-tissue; (6) The patient can get out of bed in a few days; (7) A good result is quickly obtained.

COMMUNICATIONS.

NON-OPERATIVE METHODS OF TREATING ANAL FISSURE OR IRRITABLE ULCER OF THE RECTUM.*

LEWIS H. ALDER, JR., M. D.,† PHILADELPHIA, PA.

When anal fissure is of recent origin and not associated with much spasm of the sphincter muscles, there is a fair prospect of cure without operative procedure.

This statement is made advisedly and in the face of a criticism, published in *Mathews' Medical Quarterly*, ‡ of the writer's brochure, "Fissure of the Anus and Fistula in Ano," ‖ in which the following statement is made: "It is a pity that this admirable little work wastes so much time in discussing the palliative (?) treatment of the disease [fissure]. In an affection so simple in its etiology and pathology, and that can be so quickly and radically cured by divulsion of the sphincters, it seem a great loss of time to talk about applying ointments, when it is a recognized fact that not one case in ten is ever benefited by their use."

I do not doubt that the reviewer honestly expressed himself in the statements quoted; and furthermore that the opinion given—that not one case in ten is ever benefited by other means than operative measures — is based upon personal experience. But I must be pardoned for dissenting from the same views, as my experience, whilst not an extensive one, is ample to justify a more conservative treatment of many of these cases.

I am well aware that the operative treatment of fissure is a simple procedure and that the disease is quickly cured by its execution; but I am likewise conscious of the fact that many persons object strenuously to any operation.

No matter how trifling its import be to the surgeon, an operation to the patient is something which is dreaded, and it behooves the practioner to remember that the majority of persons are unwilling to submit to operation until they are personally convinced that such a course is the ultimatum.

It is my purpose in presenting this paper to indicate how over 75 per cent. of the cases of fissure of the anus which have come under my observation, both in hospital and private practice, have been cured by non-operative measures. No less an authority than Allingham¶ states that the curability of this lesion does not depend upon the length of time it has existed, but rather upon the pathological changes it has wrought. He also adds that he has cured fissures of months' standing by means of local applications, where the ulcers were uncomplicated with polypi or hemorrhoids, and where there was not any marked spasm or thickening of the sphincters.

It is essential to the success of the treatment of fissure by local applications, that rigid cleanliness of the parts be maintained; for this purpose the anus and the adjacent portions of the body should be carefully sponged night and morning and after each stool with tepid water. It is also highly important that attention be given to the condition of the patient's bowels. Regularity of habit should be established, and the evacuation rendered semi-fluid—as figured or hard stools materially aggravate the symptoms.

To accomplish these purposes, enemata or mild aperients should be employed, and the diet must be regulated, the use of bland and unirritating food being enjoined.

All drastic purges should be avoided, as they are more or less irritating to the extremity of the rectum. To establish a daily evacuation of the bowels and to render the movement as painless as possible, I am in the habit of ordering an enema of warm water, or one of rich flaxseed tea, say from half a pint to a pint, to be administered every evening; preference being given to the night time, as then the

*Read before the American Medical Association, June, 1894.

‖ Physicians' Leisure Library Series, 1892. Geo. S. Davis, Publisher, Detroit, Mich.

¶ "Diseases of the Rectum," fifth edition, London, 1888, page 215.

patient can assume the recumbent posture, which, combined with the rest, affords the most relief from subsequent pain.

If the first enema proves ineffective, it should be repeated in half an hour. In order to relieve the pain and spasm of the sphincters attending the evacuation, it is well to use a suppository about half an hour before the injection is employed, consisting of:

℞ Ext. belladonnæ..... ½ to ⅓ grain
Ext. opii aq..... ¼ to ⅓ grain
Ol. theobromæ..... 10 grains
Misce et fiat suppositoria j.

Or an ointment of conium may be used as recommended by Mr. Harrison Cripps:*

℞ Ext. conii..... ʒ ij
Olei ricini..... f ʒ iij
Ung. lanolinii.....q. s. ad ʒ i j

A small quantity of this ointment should be smeared on the part five minutes before expecting a motion, and again after the bowels have been moved.

In applying any of the various local remedies to an anal fissue it is necessary first to expose the ulcer to view, which can be done by means of the fingers of the operator or his assistant, and to anæsthetize its surface with a 4-per-cent. solution of the hydrochlorate of cocaine, well brushed in with a camel's-hair pencil or with a piece of cotton attached to a probe. The application of the cocaine may have to be repeated once or twice, at intervals of three or four minutes, in order to obtain the desired anæsthetic effect. If any ointment has been used about the fissure, the anus should be subjected to a hot-water douche before using the cocaine, as this drug will not exert its anæsthetic influence on a greasy surface.†

Among the different remedies that have been used in the local treatment of fissure of the anus may be mentioned the following: Nitrate of silver; acid nitrate of mercury; fuming nitric acid; carbolic acid: sulphate of copper; the actual cautery; and chloral hydrate.

Of these topical applications the nitrate of silver is the best. Its effects are various: it lessens or entirely calms the nervous irritation which is so important a factor in producing spasmodic contraction of the sphincters; it coats and shields the raw and exposed mucous surface by forming an insoluble albuminate of silver; it destroys the hard and callous edges of the ulcer, and tends to remove the diseased and morbid action of the parts.

The form in which I usually employ this salt is in solution (from 10 to 30 grains to the once). The stick caustic may be also used.

To accomplish the best results, the solution should be used once in twenty-four or forty-eight hours, according to circumstances. It may be applied by means of cotton attached to a silver probe or to a piece of wood.

The application is made by separating the margins of the anal orifice with the thumb and index finger of the left hand, and introducing into the anus the probe charged with the solution. The argentic nitrate is to be applied to the fissue only; a few drops are all that is required. If thorough local anæsthesia has been induced by the use of cocaine, the application of the silver salt produces little (if any) suffering, for by the time the anæsthetic has lost its effect the otherwise acute pain of the nitrate of silver will have passed away.

After each application the part should be smeared well with an ointment of iodoform (30 grains to the ounce). The odor of that drug may be disguised by the addition of a few drops of attar of roses. Iodol may be used instead and in the same way, but I prefer the iodoform, owing to its anæsthetic qualities.

After the ulcer has been touched once or twice with the silver solution, the effect will be, in the cases that are benefited by this treatment, a considerable mitigation of the pain from which the patient suffered when at the closet and afterward, and the sore will present a healthy, granulating appearance and will slowly contract in size.

Unless the fissure be complicated with some other affection, in children and in young persons it is almost always curable by adopting the mode of treatment laid down.

Some authorities speak highly of the use of the acid nitrate of mercury, fuming nitric acid, carbolic acid, the actual cautery, etc., but in my opinion their employment is attended with more suffering than follows the use of the nitrate of silver.

*"Diseases of the Rectum and Anus," second edition, London, 1890, page 189.

†W. P, Agnew. M. D., "Diagnosis and Treatment of Hæmorrhoids. etc.," second edition, San Francisco, Cal., 1891, page 91.

The daily introduction of a full-sized bougie, made of wax or tallow, will sometimes act beneficially in cases of fissure by stretching the sphincter and producing such an amount of irritation as will set up a healing process in the ulcer. An application of cocaine or of belladonna ointment should be made to the part previous to the employment of the bougie.

In the treatment of anal fissure Allingham strongly advocates the local use of the following ointment:

℞ Hydrarg. subchlor..... 4 grains
Pulv. opii
Ext. belladonnæ } āā..... 2 grains
Ung. sambuci..... 1 drachm
M. S.: To be applied frequently.

He states that he had many cures with this ointment alone. Another excellent ointment recommended by the same authority, is:.

℞ Plumb. acetatis
Zinci oxidi } āā..... 10 grains
Pulv. calaminæ..... 20 grains
Adipis benzoinat..... ½ ounces
M.

An ointment of the oxide of mercury, 30 grains to the ounce, has cured many cases.

In conclusion, I would emphasize the fact that in many cases anal fissure, uncomplicated with other rectal affection, is curable by means of non-operative methods of treatment.

A SUGGESTION UPON THE PREPARATION OF THE FINGERS AND NAILS FOR SURGICAL OPERATIONS.*

OSCAR H, ALLIS, M. D., PHILADELPHIA.

The nails form no mean part of a surgeon's outfit. As a covering to the finger they give confidence; in the threading of needles they are often indispensabl e while often, when working among adhesions, they may serve a good turn. If the nails are too long they are in the way, and if too short, a privation. A medium length of nail is an exceedingly valuable helper at times. With some the length of nail is governed by the ability to keep it clean. Hence the nail is kept very short —much to the disadvantage of prehension, in which man excels.

The surgical care of the nails has had its full share of attention. The nail-brush forms a part of every physician's and surgeon's outfit. It is cheap, compact, and moderately thorough. Its disadvantages are that if stiff it is apt to scratch the hand or cut beneath the nails; if soft, it is of little value. To supplement the defects of the brush, some persist in using the point of the nail blade of their pocket-knifes. I say persist in using—as much has been written against the practice. Not only is there danger of cutting the flesh beneath the nail, but it leaves the under surface of the nail rough, making it a ready collector of filth, and less easily cleaned for a subsequent operation.

To avoid the knife I have long used a little wedge-shaped piece of soft pine. This, when wet, frays up, makes a kind of mop, is a good carrier of soap, and enables me to wash out under the nail. The objection to my device was that the pine too rapidly frayed out, became bulky, and required frequent trimming. Finally I hit upon the rubber eraser. A variety is made for artists and school-children that is wedge-shaped. This is ready for use as it is found at the stationer's, though if made a little sharper it is softer and more like a mop. It is pliable, soft, and an excellent carrier of soap.

For the hand, generally the old-fashioned wash-rag cannot be improved upon. It is a good carrier of soap, and with it each finger in turn can be tightly caught and wrung until it is clean. With the nail or hand-brush only the back and front of the fingers get the scrubbing.

In addition to the implements usually deemed important for the cleanliness of the under surface of the nails, a very valuable one is the nail itself. Noticing that a young lady's fingers whom I frequently met were always exceedingly neat, I make bold to ask her method, and was surprised to find that she had nothing more modern than a pair of scissors to trim her nails, and that with wash-rag and the tips of her finger-nails she kept her hands in most perfect order. One thing that may be said of the finger-nail as a nail-cleaning instrument, is that it will not scratch the under surface of the nail, a very important factor in the process, whether one aims at beauty or cleanliness.

*Read before the Philadelphia County Medical Society, June 13, 1894.

ADENOID GROWTHS IN THE DOME OF THE NASO-PHARYNGEAL SPACE.*

J. MORRISON RAY, M. D., Louisville, Ky.

I desire to ask your consideration for an affection of the glandular circle, that under normal conditions surrounds the upper respiratory passages. It consists of an hypertrophy of the collection of lymphatic tissue in the dome of the naso-pharyngeal space and has been variously called hypertrophy of Luschka gland, enlargement of the pharyngeal tonsil or adenoid and lymphoid growth in the roof of the naso-pharynx.

The frequency with which we see children allowed to suffer for years without the recognition of a trouble that leads to a blocking of the naso-pharyngeal space, which, besides interfering with the proper physical development of the child, lays the foundation for an ear trouble that lasts throughout life, is a sufficient reason for presenting the subject for consideration.

It is desirable that the general profession with whom this class of sufferers first come in contact should be apprised of its importance and the promptness with which relief can be obtained.

Recent investigations seem to throw considerable doubt on the question as to whether the normal naso-pharynx contains any visible enlargement of lymphatic tissue. There is no doubt that the mucous membrane in this region abound in submucous collections of lymphoid masses continued upward from the visible aggregation between the pillars of the fauces. What constitutes a healthy appearance of this region is still in dispute.

In my expenience in adults, the normal vault of the pharynx is perfectly smooth, and when I have found depressions, folds, or thickening, there have been symptoms giving evidence of naso-pharyngeal discomfort and a history that pointed to the probable existence in childhood of adenoid growths. In children examinations by the rhinoscopic mirror is often impossible and therefore we must depend upon the results of exploration by the finger or post mortem appearance. The former is not usually resorted to unless there are symptoms pointing to this region and the latter has not in my knowledge been extensively undertaken.

Wright claims "That the vault of the normal pharynx in the infant is a comparatively smooth walled cavity."

The investigation of Killian and Swain seem to show that the so-called Luschka's tonsil has an inconstant embryonal existence, and does not present as such in the normal adult throat, or even often in childhood.

Meyer found 1 per cent. present in 2,000 examinations, Chappell in 2,000 school children examined for the prevalence of throat diseases 3 per cent. had adenoid tissue in abundance. Bliss out of 405 children discovered adenoid in 79. Bronner claims that 4 or 5 per cent. of all children have naso-pharyngeal obstruction from these growths.

We must therefore look upon the presence of visible adenoid tissue in the vault of the pharynx as a pathological condition, often present in childhood, rarely existing in the adult, but like its analogues—the faucial tonsils and the lymphatic tissue lower down in the intestinal tube, begins to atrophy as adolescence is obtained.

During childhood the lymphatic system enjoys its greatest activity, hence at this time they are prone to become the seat of pathological changes that interfere with their nutrition or retrograde metamorphosis. They are often associated with enlarged faucial tonsils and with cervical adenitis.

Heredity plays a part in their development. All observers agree to have seen a number in one family, I have operated on two in the same household. The condition may be congenital.

I have under observation now an infant six weeks old, brought to me for a purulent ophthalmia, in which the mother says there has been difficulty in nasal breathing and a peculiar noise that indicates some obstruction in the naso-pharynx since birth. The child has difficulty in feeding, frequently relinquishing its hold of the breast in order to get air. Examination through the anterior nares shows patulent nostrils, and there is

* Abstract of a paper read before the Louisville Medico-Chirurgical Society, March 23, 1894.

not present excessively enlarged faucial tonsils: The throat space is so small I cannot get my finger well into the vault, yet I am certain that the naso-pharynx contains a quantity of adenoid growths and will require removal before relief is obtained.

Bosworth asserts that a constitutional condition difficult to definitely describe and only one step removed from scrofula, is present in all cases. Racial conditions play an important part. The Jewish race seem to suffer the most. The negro race are remarkably free from this condition; from their well known proneness to suffer from so-called strumous affections this seems anomalous. Yet in my service at the Universary Dispensary where the colored race largely predominates and where so-called scrofulous eye diseases flourish I have encountered in two years, only one case of well defined adenoids and that was a mulatto with the facial type of the Anglo-Saxon. Among the exciting causes the most important is diphtheria and the exanthematous fevers, especially scarlet fever, the patient or his parents being unconscious of any difficulty in nasal breathing until after these diseases. Climatic condition and repeated attacks of so-called head colds probably favor actively in the lymphatic tissue and thus enlargement of adenoid growths.

Woakes prefers the name "Lymphoid Papillomata" and argues that since in their local appearance and tendency to spontaneous disappearance after puberty like warts on the hands, etc. that this is the better name.

In young subjects the amount of fibrous tissue present seems to be small; but when found in children of ten or twelve years of age the growths are much firmer to the touch, less likely to bleed when handled and when examined microscopically show a far more abundant development of fibrous and connective tissue and less so-called lymphatic tissue. This condition will be found to have considerable importance in deciding the method of operation for their removal.

The diagnostic symptoms are both local and general. To one accustomed to see such cases, the facial expression, the round shoulders, and contracted chest are often sufficient. The so-called adenoid physiogomy is familiar to many—consisting of a pinched nasal aspect, elongated face, open mouth, listless dull expression, a peculiar dead nasal twang to the voice and lateral compression of the chest with marked prominence of the sternum, so-called pigeon breast, and more or less prominent in well defined cases. The respiratory symptoms are those of mouth breathing, especially bad at night, constituting the snorer, with restless, loud breathing, frequently interrupted by paroxysms of suffocation and wakefulness. The local symptoms are found both in the nose, throat and ear. The nose generally shows some turgescence of the turbinated, rarely deviation of the septum, and often more or less anterior discharges of mucus that frequently excoriate the nostrils due to the child's inability to blow the nose. The lips will be dry and often fissured, and the tongue furred from mouth breathing. A condition present in many cases is the high arched palate and contracted jaw, with irregular and decayed teeth. I have recently seen a case operated upon, one and a half years ago, in whom the teeth were much distorted and decayed, and a dentist has stated to me that the teeth were much more amenable to treatment since the removal of the cause of the mouth breathing.

I am convinced that cases of excessively enlarged faucial tonsils have always associated with them adenoids, and frequently masses of lymphatic tissue can be seen studded over the oro-pharynx, or as a ridge passing up the lateral walls.

Since the disease is almost entirely confined to children between the ages of three and fourteen, it is often impossible to view the naso-pharynx by the aid of the mirror, therefore, the final point in diagnosis must be made by exploration of the pharyngeal vault by means of the finger. The index finger passed gently into the mouth and against the back-wall of the pharynx can be carried up behind the palate, and the region of the naso-pharynx thoroughly explored. When passed well up the posterior, free edge of the nasal septum and the opening of the nares can be easily felt; on either side, the pharyngeal mouth of the eustachian tube are readily recognized, and the vault swept by the end of the finger.

The symptom depended largely upon by Bosworth, is the spraying of vaseline into one nostril, and if there are no adenoids present, the clouds of vaporized oil will

return through the opposite nostril,—if adenoids are present, no return is noticed from the other nostril. This symptom I am convinced, is of little importance, for the vapor will return unless the naso-pharynx is completely occluded, and when this condition is present, the diagnosis is self evident from other well-known symptoms. Numerous other symptoms have been dwelt upon by various writers but are, I think, of minor importance and only corroborative.

One of a general nature dwelt upon by Guye is what he calls aprosexia and consists of mental hebetude, headache, listlessness, inability to fix the attention and show progress in learning. He claims that this is due to the intimate connection of this region with the cranial cavity through the numerous openings for lymphatics and blood vessels in the sphenoid bone and interference with lymph drainage from the cranial cavity. Others have verified these observations and claim marked improvement in the mental condition by removal of the obstruction.

To my mind the most important lesion resulting directly from this disease is the interference with the organs of hearing. Happily the modern otologist has begun to recognize the fact that the majority of ear troubles are due directly to diseases of the naso-pharynx, and therefore routine examination of these parts is carried out. The majority of adenoid subjects first seek relief for ear trouble. The exact causes of the ear disease present has not been definitely settled. Whether it is due to direct obstruction by pressure of the growth against the mouths of the eustachian tubes, whether to interference with ventilation by preventing the free entrance of air into the naso-pharynx, whether by direct extension of the frequent attack of acute inflammation to which these growths are prone, or to stagnation of the return circulation by pressure of these growths upon the pharyngeal veins, as suggested by Blake, is of no importance from a therapeutic standpoint; probably all are factors, for we do not find abundant tissue or decided obstructed breathing in all cases with ear complications. Blake estimates that 80 per cent. of children with adenoids have ear trouble. The ear trouble consists in recurring attacks of acute middle ear inflammation with suppuration or not, frequent during the winter when children are exposed to the influences of winter changes. These attacks eventually lead to chronic deafness or pus discharges that resist all local medication.

Barrett and Webster, from a study of two hundred cases, go so far as to say that not only are all the middle ear diseases of children traced to the presence of these growths, but the deafness of adults is largely dependent upon the presence of adenoids in earlier life, and thus the establishment of changes that produce later on permanent ear disease.

The treatment of these growths depends upon their character, size, the age of the patient, and the symptoms requiring relief. No doubt attention to the general health by the administration of constructives is often indicated, for by correcting anæmia and aiding in tissue building we hasten growth in the child, and as the naso-pharynx enlarges, the growths are carried farther from the soft palate and the breathing space is correspondingly increased. In my experience local application of medicaments such as caustics or astringents are of no importance and simply produce pain without alleviating the symptoms or lessening the obstruction. The only sure and prompt relief is a surgical one. The methods of procedure advised are, the use of variously constructed forceps, curettes, snares, the galvano-cautery and the finger nail. The galvano cautery is difficult to use in children, dangerous when anæsthetics are administered, and slow in its results, besides it is the most liable of all methods to excite ear inflammation. Snares are difficult to manipulate in the naso-pharynx, and unless the growths are large and pedunculated, a failure to engage them in the loop is probable. The method therefore lies between forceps, curettes, and finger nail. If the growths are abundant, soft and friable, the finger nail can scrape them out quickly and without danger. If they contain considerable fibrous tissue, forceps or curette are required. I have tried the different shaped forceps, but have now discarded them in young children for the improved Gottstein curette, which, if properly used is free of danger to surrounding parts, and the manipulation is quickly accomplished. The question of anæsthesia depends upon the age and tractability of the child. If chloroform is administered the hanging head position must be obtained, lest the

free flow of blood that follows may produce asphyxia. The amount of blood lost is usually not great, while quite free for a few seconds, it quickly stops spontaneously.

In children twelve to fourteen years of age, the post-nasal forceps will often be required as an adjunct to the curette, and if the growth is firm to the finger, the forceps are often alone satisfactory. The Gradle instrument grasps a large piece at one bite and I have found them valuable. In the after treatment nothing is required beyond quiet for a few hours, and keeping the parts free of infection by antiseptic washes. No operation can be considered a success that does not remove all the offending tissue. In my earlier work I attempted to remove them without an anæsthetic, and with forceps; rarely was I able to induce a child to allow the introduction of cutting forceps more than once or twice, but little relief was attained, and I was inclined to believe possibly there was some return. The results of the operation are as satisfactory as any in surgery. The improvement in general health is often remarkable. Jakin reports a case which in two years, a boy increased in weight from 105 to 140 pounds and in height from 5' 3" to 5' 10". Often without internal treatment in a few months the ruddy complexion and increased general vigor is noticeable to all. The family express satisfaction for the relief the operation gives to recurring earaches and ear discharges, and the change in the character of breathing. While we find these growths in children the remnants alone are noticeable in the adult, yet the roughened surface left in the naso-pharynx and the bands of adhesions to the eustachian tubes produce synachia that interferes with its function, and gives rise to permanent ear trouble, and chronic post-nasal discharges that resist all treatment.

I have given a reveiw of the subject to excite discussion and to attract the attention of the society to an often neglected region. I can briefly summarize what I wish to emphasize as follows:

1st. The majority of cases of chronic nasal obstruction in children are due to the presence of adenoids in the naso-pharynx.

2nd. Mouth breathing, snoring, wakefulness, defective mental developement, bad teeth, deformed chests and deafness result from this obstruction.

3rd. The recurring earaches and pus discharges from the ear persistently resisting treatment directed to the ear, are the result of the presence of adenoids and in a majority prompt relief follows surgical removal of the growths.

4th. Many of the ear diseases of adults, and so-called post-nasal catarrhs are the result of adenoids that had not been recognized or treated in early life.

5th. That while adenoids will apparently disappear, as adolescence is attained, they never entirely atrophy. but leave fibrous stumps and adhesion to the eustachian tubes.

6th. Operation for their removal should be undertaken under an anæsthetic and thorough removal accomplished.

7th.—The operation is reasonably safe and besides giving decided relief to the local symptoms in the throat and ear often show wonderful improvement in the general physical condition.

PRELIMINARY REPORT ON THE DIAGNOSTIC VALUE OF PEPTONURIA AND INDICANURIA.*

JOHN H. MUSSER, M. D., AND F. SAVARY PEARCE, M. D., PHILADELPHIA, PA.

The following observations have been made from time to time during the past six months by the writers in order to determine the diagnostic value of the presence of the above-mentioned constituents of urine in disease, and to observe the practicability in daily practice of the methods employed to detect their presence. It is our purpose to continue on a more extended scale the observations here begun.

The specimens of urine studied were taken mostly from the medical wards of the Presbyterian Hospital. Through the kindness of Dr. Abbott, the testing was in the main done in the Hygiene Laboratory of the University of Pennsylvania. Our

*Read before the Philadelphia County Medical Society, June 13, 1894.

appreciation of the aid of the resident physicians, Drs. Arnold, Swan, and Johnson, is hereby acknowledged.

1. Tests. — Von Jaksch† gives two methods for testing for peptone in the urine. The first, that of Hoffmeyer, is far too complicated and is not, therefore, detailed. The second, the "Devoto method," is given as the best, and is the one here used. The principle lies in the exclusion as far as possible of all other albumins. It is as follows: Take 200 to 300 c.c. of urine, to which add pure crystals of ammonium sulphate in proportion of 80 grammes of the sulphate to 100 c.c. of urine. This solution is placed in a beaker in a boiling-water bath for one-half an hour, when the greater part of the salt should be dissolved. It is then steamed in Budenberg's steam sterilizer for another half hour, the vapor being kept at 100° C. By this procedure, all proteids (serum albumin, globulin, hæmoglobulin, deutero-albumose, peptone, nucleo-albumin—*i. e.*, mucin) are precipitated; but the serum albumin and globulin and nucleo-albumin are thus the only *thoroughly* coagulated bodies, the hæmoglobulin being only *partly* coagulated.

After this last heating to 100° C. filter at once. The filtrate should be straw-colored and free from albumin, as indicated by boiling or the potassium ferrocyanide†† tests. A *slight* cloudiness appearing with the ferrocyanide test does not necessarily imply the presence of albumin. A *decided* turbidity or precipitate would be due to a proto-albumose, or, more probably, hetero-albumose. Should the hot filtrate be cloudy or give the proteid reactions, the investigation has miscarried and must be repeated from the beginning. The residue is washed first with *hot*, then with cold water. The resulting filtrates show a more or less decided brownish tint. These are collected, and to one portion of the fluid acetic acid and potassium ferro-cyanide solution are added to test for albumin. Should no result be obtained the biuret test is performed with a portion to which caustic soda or other alkali has been applied in excess. Any albumin shown to be present is *certainly* peptone.

The filtrate from the *hot* washings may exhibit it, but it often happens that the peptone *first becomes recognizable with the biuret test* in the filtrate derived from the *cold* washings.

Several specimens, both of the hot and cold washings, may be tested until a positive result is obtained.

The test for peptone is, therefore, at best very delicate and requires much time to work out. The biuret reaction is that by which the color test (for such it is) for the peptone is obtained, as inferred from the above. It is as follows. Urine: Add caustic potash, caustic soda, or ammonium hydrate in excess; then add, drop by drop, solution (10 per cent.) of copper sulphate. If *albumin* be present the resulting peroxide of copper (a green precipitate) is dissolved, and the fluid assumes a *reddish-violet* color.

Peptone strikes red, not violet, in the fluid. As this reaction is probably not familiar to many, the color produced is here exhibited (and in a less intense degree than it is usually found in peptonuria experimentation) by adding albumose, containing peptone, to the test.‖

The test for indican is much more simple, and, as given by Strümpel,§ is as follows: "We mix equal volumes of urine and officinal hydro-chloric acid (P. G.), and then add, drop by drop, a concentrated solution of chloride of lime, shaking it after each drop is added. If the urine contains *much* indican, a decided indigo-blue color appears." To this may be added, that the test can be brought out more clearly, chloroform, then agitating. After standing, it will be found the chloroform at the bottom of the tube will be colored violet or bluish.

2. Origin of Peptone.—In health peptone is produced in the blood by the act of digestion. We know that the proteids ingested are transformed into peptones in the stomach and intestines. The peptone is reconverted into proteids in the circulation. Peptonization is, therefore, the *sine qua non* for absorption of proteids. In health the peptone is immediately transformed on entering the blood, hence the reason for the statement of physiologists that "peptone is not found normally in the blood of urine."

The occurrence of peptones in the blood

† Clinical Diagnosis, p. 255.

†† This test is as follows: Urine if filtered and then acidulated with acetic acid Then add a few drops of a 10 per cent. solution of potassium ferrocyanide. If the urine becomes turbid it shows presence of albumin.

‖ Showed test-tube with reaction.

§ A Text-book of Medicine, p. 408.

or urine in disease would show over-production or a lessened power of the system to assimilate it.

G. Bjorkman's‡ excellent paper throws out some suggestions as to the rationale of peptonuria. He says: "If we regard the chemotactic influence upon absorbed peptones as the reason for such increase in the number of white corpuscles during digestion, many obscure mysteries in the physiological phenomena of absorption will be cleared up."

From the above statement we can infer that an excess of peptone, because the digesture and absorptive power of the white blood-cells are impaired, is carried off as waste in the urine.

The leucocytes multiply for defence in septic and other hæmolytic cases, and some become pus cells, undergo degeneration and furnish increased peptone in the blood, which is then carried off in the urine.

3. ORIGIN OF INDICAN—Indican is found normally in the urine in small amounts. Chemically indican is indoxysulphate of potassium and is colorless, but on adding strong acids or oxidizing agents indigo is set free, producing a blue color.

Its origin in health is hardly established.

In disease indican is likely formed from indol, a product formed in the small intestines by the decomposition of albumin and other substances under the influence of bacteria.

4. CLINICAL SIGNIFICANCE OF PEPTONURIA (*i, e., excess of Peptone.*)—As before stated, peptone is not found normally in the blood or urine. It cannot, at least as yet, be detected so frequently or easily in any case as serum-albumin. Peptone is especially found in the urine, according to von Jaksch and other authors, in septic conditions, and under all circumstances where pus is formed in the body—*e. g.*, tubercular cavities, as in the lungs, abscesses, etc.

Von Noorden, however, in his recent work, *Lehrbuch der Pathologie dis Stoffwechsels* (Berlin, 1893), does not think peptone is found in the urine. On the other hand, Robitschek has recently done some experiments for von Jaksch. An abstract of their work appears in *The Practitioner* for June 4. These authors lay stress upon "*The Significance of Peptonuria.*"

"‡The Physiological Role Played by the Leucocytes," American Medico-Surgical Bulletin for January, 1894.

5. CLINICAL SIGNIFICANCE OF INDICANURIA (*an excesi of Indican*).—Osler* gives, under the head of "Anomalies of the Urinary Secretion," some eighteen substances that may be found in abnormal urines. Some of these are detected in small amounts in health; others being considered always as abnormal, so far as is known to-day. He further states that indican, when in excess in the urine, often denotes "chronic constipation or ileus."

Strümpell† refers to the same thing, as does one of the authors.§ Indican is also said to exist in some cases that are not on a strict milk diet; in wasting diseases, especially if secondary to gastro-intestinal diseases; in peritonitis and empyema, and especially where large quantities of albuminous matter are undergoing rapid decomposition in the intestinal tract. On the contrary, in catarrhal jaundice and in cirrhosis of the liver some clinicians say it is found in very small amounts only. Indican may be thrown down before the urine is voided, but usually, when present, is found after that secretion cools outside the body.

The following observations here tabulated,‖ as to peptone, indican, albumin, and uric acid in the urine, of the total number of specimens examined are too few in number to base conclusions of a definite character. As to peptonuria and indicanuria, they support in the main the foregoing statements.

We were engaged at the time in studying the urine of cases of typhoid fever. We take this opportunity of presenting the results of the examination for peptone and indican in this disease. Thus in twenty-two experiments in twelve cases of typhoid fever, fair reactions for peptone were obtained in three cases only, while the indican test detected that substance in excess in sixteen out of the twenty-two tests.

In one of the three cases there was a large number of boils, which accounted for the peptonuria. In the other two no foci of suppuration could be found. Such focus was probably present.

CONCLUSIONS: 1. It can be said that peptonuria does not occur in typhoid fever

*The Principles and Practice of Medicine, pp. 772 to 777.

in the natural course of the disease.

2. Its presence would point to some area of suppuration.

3. Indicanuria is common to typhoid fever, and indicates the continuance of an intestinal putrefaction. May it not be possible in cases of typhoid fever, with a fibrile course continuing after the specific symptoms have subsided, to determine by this test whether the said fever is due to the persistence of intestinal lesions or to a remote process? and the absence of indicanuria, therefore, point to the removal of any intestinal complication?

The number of cases *other* than typhoid fever examined were forty-five. Many specimens were repeatedly examined as checks, making in all seventy-two tests, not including the typhoid cases.

We shall not burden you with the reading of the long tables here shown, but simply summarize the disease and findings under each head.

1. Cases With Absence of Peptone in the Urine.—There were twenty-one cases out of the forty-five cases examined in which no peptone reaction was found.

Five out of the twelve known septic cases contained no peptone in the urine. In two of these cases, of old well-draining tubercular sinuses, the pyogenic membrane probably acted as a dam, producing for practical purposes local diseases, not affecting the system, as a dyscrasiæ.

The one appendictis case (out of three tested) not having peptonuria was of mild type and recovered without event. There was no generalized morbid process.

Among the remaining cases where no peptone was found in the urine were those of various diseases in the medical wards, mostly doing well, such as corneal ulcer, supposed abscess of groin (proving on operation to be a dermoid cyst,) hysterical hemiplegia, septic stump, (making a rapid recovery,) hysterical hemiplegia, influenza, articular rheumatism (subacute,) bronchitis, hysteria, chlorosis.

Cases in which no Peptone was found in the Urine:

Appendicitis	1	Pneumonia (mild)	1
Bronchitis	1	Neurasthenia	1
Bright's disease (mild)	1	Rheumatism (articular)	1
Chlorosis	1	Rheumatoid arthritis	1
Catarrhal gastritis	1	Sciatica	1
Corneal ulcer	1	Septic stump (rapid recovery)	1
Epilepsy	1	Septic condition of groin (proved to be dermoid cyst at operation)	1
Hysterical hemiplegia	1	Tubercular bone disease	2
Hemiplegia (organic)	1		
Hysteria	1		
Influenza	1		
Pleural effusion (slight)	1		
		Total	21

2. Cases with the Presence of Peptonuria.—All the cases in which suppuration was known to be present had peptone in the urine except two. Of the two out of three appendicitis cases that showed peptonuria, one recovered; in the other perforation took place. Operation was done, finding much pus, the patient dying of septic peritonitis.

In all the forty-five cases (excluding the ten septic ones) peptone was found among the miscellaneous diseases (thirty-three) in twenty-four, such as Bright's disease, pneumonia, pyothorax, pulmonary tuberculosis, chronic valvular disease of the heart with extreme anæmia, pleural effusion and in such diseases where there was destruction of the *blood cells*.

Cases in which there was Peptone in the Urine:

Anæmia (extreme)	1	Pneumonia (severe type)	2
Acute general dermatitis	1	Pleural effusion (marked)	1
Appendicitis	2	Pyæmic or septic cases	
Bright's (chronic)	1	(out of the 12 examined)	10
Chronic valvular heart disease with anæmia	1	Typhoid (covered with boils)	1
Gelatinous arthritis knee	1	Tuberculosis	3
		Total	24

In the case of septicæmia with retained secundines in which there was also marked reaction for peptone there was extreme leucocytosis, the blood estimation revealing the following: white blood-corpuscles equals 49,966 to c.mm.; red-blood corpuscles equals 3,925,000 to c.mm.; hæmoglobin, 43 per cent. This is confirmatory evidence of what takes place in the blood in septic conditions. It may probably, *a priori*, be that leucocytosis is generally found to accompany peptonuria. With this cell disintegration, too, according to Victor Vaughan* and others, the corpuscle nuclei being destroyed furnishes xanthin and uric acid in excess in the urine.

3. Cases in which there was Little or No Indican in the Urine.—Out of the forty-five cases of miscelloneous diseases (thus still excluding the twelve typhoid already classified) formulation of the findings is as follows:

a. In thirteen diseases, including epilepsy, Bright's disease, hemiplegia, pneumonia, tuberculosis, and rheumatoid arthritis, indican was entirely absent or only the faintest blue color was produced which was then assumed as physiological.

*"Nuclein and Nuclein Therapy," Journal of the American Medical Association for June, 1894.

Cases in which there was Little or No Indican in the Urine:

Of the pyæmic cases, 4:	Abscess (buttock)	1
	Infected wound	1
	Tubercular bone disease	2
Miscellaneous, 13:	Amputated stump	1
	Arthritis (rheumatoid)	2
	Arthritis (gelatinous)	1
	Bright's disease	2
	Corneal ulcer	1
	Epilepsy	1
	Hysteria	1
	Pneumonia	1
	Neurasthenia	1
	Tuberculosis, lungs, (incipient)	2
	Total	17

4. CASES IN WHICH INDICAN WAS PRESENT IN VERY APPRECIABLE TO MARKED AMOUNTS IN THE URINE.—We found indican in twenty-five of the forty-five cases examined (excluding again the typhoids.")

In general the diseases included pleural effusion with intestinal catarrah, catarrhal gastritis, nervous dyspepsia, and all three appendicitis cases from a good to marked reaction.

Indican was also found in excess in the case of cancer of the uterus. When thus found in the urine in local cancer, indican may be of value as showing secondary nodules in the intestines, or at least deficient and altered functionation produced by the malignant disease.

Indican was also found in the urine of the case of sapticæmia from retained secundines. Here the close poximity of the focus of pus to the intestinal tract most likely was the cause of the fermentation in the gut.

We were unable to obtain any cases of intestinal obstruction for examination during the time of making these studies.

Cases with Indican present in Excess in the Urine:

Abscess (psoas and lumbar near intestinal tract)	3
Appendicitis	3
Acute dermatitis (bowels torpid)	1
Anæmia (extreme) with constipation	1
Articular rheumatism	1
Chronic valvular heart disease with subacute intestinal catarrh	1
Chlorosis (with constipation)	1
Cancer, uterus	1
Catarrhal gastritis	1
Dermoid cyst	1
Hysterical hemiplegia	1
Hysteria, anæmia, and constipation	1
Hemiplegia (organic) with constipation	1
Influenza	1
Pneumonia	2
Pleural effusion	1
Retained secundines with intestinal torpor	1
Sciatica	1
Tuberculosis	1
Typhoid (covered with boils and hence included in pyæmic cases)	1
Total	25

5. ASSOCIATION OF PEPTONURIA WITH INDICANURIA.—The two were found together in a large number of the cases in which either compound was detected.

Peptone occurred, as stated, in the large majority of septic cases.*

Where there was extreme emaciation with intestinal symptoms as an especially prominent etiological factor, indican was found in the urine in excess.

The relation of indicanuria with pepionuria depends on two things mainly:

a. If the septic or other irritating condition is localized in the gastro-intestinal tract marked indicanuria is detected.

b. If the general system becomes involved in the albuminous compounds, destruction, then peptone is formed in excess in the blood and hence thrown down in the urine along with the excess of indican.

Petone depends on changes really in the system.

Indican depends on fermentations really outside of the body (*in the gut*).

Thus depending on *general* cell destruction and elimination of the suboxidized proteid product, or on *local* intestinal fermentation being prominent, will peptone or indican be found in excess in the urine.

If the *local* and systemic conditions exist together as described, then we may expect to find both products in the urine. Then, too, the indication is of more serious disease.

6. ASSOCIATION OF ALBUMIN WITH PEPTONURIA AND INDICANURIA.—In the specimens of urine in which albumin was found, it was due to a definite cause, as in Bright's disease or pyuria, hence in these experiments albuminuria bore no relation to peptonuria or indicanuria.

7. Likewise there is negative result in these few experiments in comparing the frequency of excess of uric acid with excess of peptone or excess of indican in the urine. The long-accepted theory of direct relation between uric acid and urea is now overthrown.

It would be, therefore, of value to test more extendedly for the relation of uric acid (know now to be produced from cell nuclei destruction) to peptonuria and leucocytosis. A great field is open here.

Finally, the trouble and time taken to this work thus far proves it not to be very practical.

But if one *had* the opportunity and time for such investigation of cases important indications would undoubtedly be derived.

*The liability to inaccuracies in the work *creeping in* must be considered in excluding peptonuria from two septic cases.

EDITORIAL.

DISCUSSION ON HERNIA AT THE LATE MEETING OF THE AMERICAN MEDICAL ASSOCIATION.

An elaborate programme had been prepared for the Surgical Section of the American Medical Association at the San Francisco meeting, in which the subject of hernia was designed to take a prominent position.

The plan of providing a number of formal papers upon a specified subject and the selection of those who are to be prepared to lead the discussion, will commend itself to all. It must be conceded, however, that in this discussion on hernia the results have been disappointing.

Many of the papers were read by title only; and most of the contributions actually presented showed signs of the hasty performance of a perfunctory duty, without such care and preparation as the dignity of the occasion demanded. Almost nothing of statistical value was produced.

The most creditable and practical essay presented, was that of Dr. Joseph Ransohoff, of Cincinnati, on the "Treatment of Strangulated Hernia." This paper, an abstract of which appears elsewhere in the REPORTER, will amply repay careful study.

The writer advises early operation in all cases of strangulation, and shows that in a large number of mortal cases, death was induced by causes preventable through early operation. This timely contribution is a painful reminder that despite the vaunting of enthusiasts on abdominal surgery, it remains an open question whether or not of late years any substantial progress has been made in the surgery of the intestine. For instance; McCosh is represented as placing the mortality of artificial anus for gangrene of the bowel at 50 per cent; Renno Schmidt gives a mortality of 85 per cent. for resection of the intestine; and of 168 cases of gangrenous intestine, Mikulicz reports 109 deaths.

Dr. Ransohoff believes that an operation for strangulation is not in itself dangerous to life. The diminished mortality of more recent years, he thinks, is due largely to an early interference, and the mortality may be further reduced by avoid-

ing such causes of death as heart failure and pneumonia, by the substitution of local for general anæsthesia. He says:

"With my present knowledge, the deaths from heart failure and pneumonia might have been averted by substituting cocaine for general anæsthesia.* * * * In a case recently seen, I made the relief-operation, removing a mass of the omentum as large as a walnut, and returned the intestine without inflicting enough suffering to elicit a moan."

This point is not sufficiently emphasized. Manley, in his recent work on hernia, recommends cocainization as a local anæsthetic in operation for all cases of strangulated hernia, claiming thereby a reduction of operative mortality to nil, unless the bowel is actually gangrenous at the time of intervention. Indeed Manley claims something more than pain-killing power for cocaine in operations for strangulated hernia, for he alleges that it prevents vomiting, acts as a local hæmostatic, and makes the surgeon so master of the situation that he needs no assistance other than that the patient himself can provide.

If the local use of cocaine in strangulated hernia is what Manley claims for it, its general adoption in this class of cases will constitute a very substantial advance in the operative treatment of this condition.

It is unfortunate that even this phase of the subject did not receive more attention at the California meeting; for if local anæsthesia provides safeguards to life, and is without immediate or ultimate peril, it should be made known to the profession, and be at once adopted in all suitable cases in which hernia becomes complicated and menaces life.

ABSTRACTS.

NATURAL SANITATION.

The natural conditions which should be incident to the life of human beings, conducive to long and healthful life are:

a. Breeding from parents free from physical or mental taint.

b. Feeding the infant upon the mother's milk.

c. Higher regard for the physical than mental training of youth.

d. Pure air, pure water, pure food.

f. Wearing loose clothing.

g. Natural sleep and plenty of it.

h. Natural labor—physical or mental unforced.

i. Dwelling house free from filth, having free access of sunlight and air.

j. Use of earth closets.

k. Prompt elimination of effete matter from the body, by the lungs, skin, bowels and kidneys.

l. Frequent washing of the body.

m. Frequent change of all articles of clothing.

n. Burning of the dead.

o. Exercise of passions within natural prompting.

p. Constant occupation, physical and mental.

INSANITATION.

The unnatural conditions incident to human life which are conducive to ill-health, disease and early death are:

a. Habits peculiar to the higher modern civilization in its influence upon both body and mind. Cultivation of luxurious living rather than following natural instincts.

b. Inheritances by breeding from parents who are physically and mentally tainted with disease, such as syphillis, consumption, rheumatism, alcoholism. Low physical development, malformations. Insanity or mental bias. Marriage between those of near family relationship.

c. Impure air. Bad ventilation, in sleeping, work, school or lecture room. Theatres, halls, churches, sleeping cars, railway, day or night ordinary passenger cars. Palace cars. Depot waiting rooms. Hotel sleeping or dining rooms. In water closets, sewers and privies.

Impure air in these places arises from expired air from the lungs and the effluvium from the skin, loaded as it always is with effete matter.

Air becomes impure from the floating dust arising from dried filth, which includes the spittle and phlegm of diseased human beings and animals. The eliminated excrementitious and effete matter from the animal or human body. From decayed rotting or fermenting waste of a vegetable or animal nature. These influences are incident to every place inhabitated by animals of high or low degree, including man, and the palace as well as the hovel may be tainted.

d. Impure water which becomes so by contact with the following influences:

Human and animal excreta, surface deposit, or in privies, cesspools, and sewers.

Kitchen refuse, bath tubs, laundries, slop water, garbage, decayed vegetable matter on surface of ground or in water. Barnyard, stock yards, pig-pens, cow and horse stables, graveyards.

Vegetable acids from soaked leaves, branches and roots of trees and bushes on water shed.

Artificial and natural manures, washed from agricultural fields on water shed.

Swamp scum and fungus growths, swamps, stagnant pools, marshy bottoms.

Low stage of water in tributaries on the water shed.

Turbid water from canals and stagnant pools.

Dead animals, fish and spawn in water, or on the surface of the water shed.

Street and road drainage, public markets, slaughterhouses, putrescent impurity from decaying animal tissue, blood and excreta.

Tanneries.—Refuse, decayed animal tissue and chemicals from the process. Sulphuric and tannic acid, bark, liquors, etc.

Creameries.—Fermenting refuse from process of cheese and butter-making.

Malt liquors, breweries, alcoholic liquor distilleries, refuse fermenting vegetable matter for them.

Paper mills, chemical pollution from lime, chloride of lime and alum, caustic alkali, etc.

Pollution by chemicals, grease oils, spent liquors, etc., wasted from dye works, chemical works, woolen works, cotton works, soap works, gas works and wool washers.

Sulphate of iron and oil of vitriol from iron and wire mills.

Drainage from coal mines, coal yards, railroads and locomotive houses.

Oil wells, natural gas wells, iron mines, bog iron ore, lead mines, lead pipes, sulphuric acid, tannic acid, lime, sulphate of lime, carbonate of lime, magnesia, salt and chlorine.

To the above may be added under the general head of sewerage, anything and everything which pertains to, and is incident to human and animal life, manufactories, trades, professions and sciences, and denominated refuse or waste.

It may be stated as a general proposition, that all waters taken from a water shed which is inhabited by human beings under the most modern state of civilization, are more or less contaminated by one or more of the various causes which have been stated.

It may also be stated as a general proposition, that all waters in a natural state, whether proceeding from the clouds as rain, or coming from the earth, contain impurities which are injurious, subject to such exceptions as may be peculiar to certain conditions and environments.

e. Communicable Diseases:

1. Insanity; syphilis; rheumatism; consumption; physical debility; alcoholism; mental bias in favor of immorality; various manias not amounting to insanity; physical deformity and nervousness.	By bad breeding, through inheritance.
2. Small-pox, scarlet fever, measles, whooping cough, skin diseases, diphtheria, puerperal fever, yellow fever. Vegetable and animal parasites and vermin.	By contract with the diseased, their clothing or surroundings. By dust arising from diseased scurf and dried effete matter from the body.
3. Typhus fever, typhoid fever, cholera, dysentery, inflammation of stomach and bowels.	By contact with filth, by water, milk or other liquids and food containing the germs of the disease.

f. Mental and nervous diseases of various types. Caused by grief, worry, anxiety, disappointment, shock from sudden joy or sorrow. Wounds: chronic diseases, inherited or induced by alcohol, morphine, opium, tobacco, coffee or tea. Diseases peculiar to the female sex. Fanaticisms, religious excitements. Physical vices or worry incident to commercial and professional life.

Of the foregoing influences which cause conditions which are at war with sanitation the most serious may be mentioned as follows:

Impure air, water and food. Filth, uncleanliness. Bad breeding. Consumption. Diphtheria. Fever of various kinds mentioned. Improper disposal of excreta, of diseased tainted clothing and furniture, and insanitary disposal of the dead by burying in the ground. Careless contact of persons one with the other, who are under the influence of disease, by association, or in any other manner. Alcohol and narcotic poisons.

Such are the conditions incident to insanitation the world over.—*W. H. Barnes, Esq., in Dietetic and Hygienic Gazette.*

SOCIETY REPORTS.

THE LOUISVILLE CLINICAL SOCIETY.

March 13, 1894.

[STENOGRAPHICALLY REPORTED BY C. C. MAPES.]

UTERINE FIBROID.

DR. W. H. WATHEN: This tumor was removed from a lady thirty-four years old, from Bowling Green, on last Thursday. She had suffered from its effects for several years, and for two years had profuse menorrhagia and metrorrhagia. She had been treated by some of the best physicians of the State without improvement, and had finally become so anæmic and feeble that her physician did not think it safe to allow the case to go longer without surgical interference, and referred her to me. Her pulse was 110, and she weighed about ninety pounds. An examination of the urine showed that the kidneys were performing their functions properly, and with the exception of extreme anæmia and a rapid and feeble pulse she was in a good condition for operation.

This tumor weighs about ten pounds and is nearly the shape of a generally enlarged uterus. The tumor had not formed adhesions, but was intraligamentous, having unfolded the broad ligaments out to their attachment to the pelvis, so that it could not be brought through the abdominal wound because held down tightly and wedged in the pelvis. Ligation was begun at the top on one side, then on the other, dividing off the broad ligaments, when the tumor could gradually be elevated. I ligated as close to the pelvis as possible and clamped close to the tumor with hemostatic forceps. The peritoneum was stripped down in front and behind, and by this means a pedicle was formed. I intended to ligate the uterine arteries and extirpate the entire uterus, or leave the cervix covered with peritoneum, but when the neck was well formed I saw it could be very easily brought into the wound and treated extra-peritoneally, and, as the woman was in feeble health, any delay might have proven serious. So I used the *neude* and treated the pedicle by the extra-peritoneal method. The peritoneum was stitched closely around the pedicle below the wire with catgut, the incised peritoneum closed for the entire length with catgut, and the abdominal incision united by silk-worm gut sutures introduced down to the peritoneal layer. There was no shock, and the anæsthetist reported the patient's pulse better when the operation was completed than when she went on the operating table. She had some pain during the afternoon, and the nurse gave two hypodermic injections of $\frac{1}{8}$ grain morphine. Aside from that she has had no trouble, has been apparently in a normal condition, pulse and temperature good, passed gas

freely within twenty-four hours after operation, bowels move daily and she is convalescing nicely. I will not change the dressing for two days.

I prefer the intra-peritoneal treatment of the stump or total extirpation where there are no conditions that indicate that the extra-peritoneal method would be safer. The extra-peritoneal method is the simpler method and quicker in many cases. In two cases recently operated upon, I used the intra-peritoneal method, ligating the uterine arteries and leaving the stump.

I am sure there will never be a time when hysterectomists will adopt any one method of treating the pedicle to the exclusion of all others.

DISCUSSION.

DR. W. O. ROBERTS: In applying the *neude* was it necessary to separate the bladder or rectum from the tumor?

DR. W. H. WATHEN: An examination before operation showed the bladder to be low, and in operating it was not in the way. The tumor was not adherent to the rectum.

DR. A. M. CARTLEDGE (Visiting): I am like Dr. Wathen. I think the supra-vaginal method the best in treating such cases. An operation of this character ought to be done very quickly. I would like to ask the reporter how much time was consumed in applying the *neude* and removing the tumor.

DR. W. H. WATHEN: The time required for that part of the work was about thirty minutes.

DR. A. M. CARTLEGE: Supra-vaginal operations like this where there are not a great many adhesions ought to be completed in forty to forty-five minutes. I have certainly done several such operations in that length of time, and this seems to me to be an ideal tumor for that procedure. In two or three cases I have had the trouble indicated by Dr. Wathen, an unfolding or infolding of the broad ligaments, and I remember one case where I actually removed such a tumor without opening the general peritoneal cavity. I always follow up and ligate first the ovarian then the uterine arteries. I think the best plan is to ligate these arteries direct and not include the broad ligament as is usually done. That is instead of transfixing the broad ligament and applying a ligature to the artery including the broad ligament, you ligate each separately, cutting down to the cervix itself which is a matter of but a few minutes. By this means hemorrhage is absolutely controlled; in fact, where this method was employed I have never seen any hemorrhage, but where both the broad ligament and artery are included in the same ligature owing to the contraction of the structures, the ligature is liable to become loosened and serious hemorrhage might occur. This method of ligation is applicable to any of the three methods of operating, total extirpation, supra-vaginal and extra-peritoneal.

I remember the first time I did this operation the time consumed was one hour and fifteen minutes, but that was in a very complicated case with extensive adhesions. I am sure in most cases it can be done in forty-five minutes.

DR. W. H. WATHEN: This was not on easy tumor to remove, for the reason that there were practically no broad ligaments to work upon. Only a small portion of tissue could be included in each ligature and the ligaments had to be cut so near the tumor that there was difficulty in controlling hemorrhage from the uterine side. Where there is unfolding of the broad ligaments, this difficulty is encountered. With a tumor that can be brought well up out of the pelvis, where there is no unfolding of the broad ligaments, the operation is very simple. In some instances it is only necessary to apply two ligatures to include the arteries upon each side; the first for the ovarian artery, the second for the uterine artery, but in the case reported, before getting down to the pedicle, it was necessary to ligate section after section. Six ligatures were used upon each side of the tumor, which made the operation difficult and tedious.

Dr. L. S. McMurtry read a paper entitled

OVARIAN TUMORS.

(See page 42 last week's REPORTER).

DISCUSSION.

DR. W. O. ROBERTS: I agree with what Dr. McMurtry has said with reference to the diagnosis of abdominal tumors. It is impossible in many cases to make the

diagnosis, as he states, without an exploratory incision. I do not suppose there is an operator living who upon opening the abdomen has not found conditions to deal with that he had not expected. As the essayist has said so simple a thing as ovarian tumor has often been mistaken for a great number of troubles. At the last meeting of this Society I reported a case of very large multilocular ovarian tumor that had been mistaken by a number of competent physicians for extra-uterine pregnancy; one went so far as to say that he believed he had felt the the movements the child. It turned out to be simple multilocular cyst. On one occasion I remember to have opened the abdomen for ovarian tumor and found as Dr. McMurtry states he did on one occasion, a large cyst of the kidney. I have operated for removal of the spleen, and found the trouble to be a tumor of the kidney. As he states also I do not think it makes much difference as to the length of the incision that we make in the removal of these tumors. My rule is to always make the incision sufficiently large to give an abundance of room.

In reference to uterine myoma: I can recall quite a number of women who had myoma of considerable size, extending up to the umbilicus, and half or nearly all of them have disappeared at the menopause. I examined a lady a short time ago who had a tumor of this kind extending above the pubes—she was also seen by Dr. Marion Sims in 1875, at the time the *American Medical Association* met in this city, and an operation was discussed at that time. Dr. Sims strongly advised against any operative procedure. In the examination a short time ago the tumor was found to have almost entirely disappeared. There is another lady in this city, a nurse who had a myoma of the uterus of considerable size extending almost up to the umbilicus. A number of the gentlemen present know the woman. Since the menopause it has almost entirely disappeared.

As regards the operation of removal of the appendages in the treatment of uterine myoma, I suppose all of us can recall numbers of cases where we have done the operation with marked success. I do not know of a single instance in which I have removed the appendages where the tumor has failed to shrink away. I do not remember to have lost a patient from an operation for this condition. I think where the tumor has not attained a very great size, and where it is not producing any trouble from pressure that the simpler operation of removal of the appendages ought to be tried before total extirpation is done.

In the operation of hysterectomy, I agree with what Dr. McMurtry has said that the operation mentioned by him, the one employed in the case he reported, is decidedly the simplest and safest of any method that I have seen. I have never done the operation of amputation through the cervix and leaving the stump inside. I have always done the operation mentioned by Dr. McMurtry—extra-peritoneal treatment of the stump—and so far prefer it to any other.

Dr. W. H. WATHEN: There can be no question about the propriety of removing ovarian tumors; it matters not how small they may be. It is fortunate that women who suffer with these tumors now solicit professional advice early and have the tumors removed before complications have arisen that would endanger life. Ovariotomy, where the kidneys are healthy, and the system is in good condition, unless some unusual complication should arise, ought to be almost universally successful in the practice of any one who has experience with the best technique in abdominal surgery. For more than two years I have met with so little trouble in ovarian tumors, that they give me less annoyance than any other form of tumor in the abdominal or pelvic cavities. The diagnosis of ovarian tumors, especially when small, cannot always be made accurately, but with the exception of fibroid tumors of the uterus they are probably more easily diagnosed than any other form of abdominal tumor. I have several times made a diagnosis of ovarian tumor but when the abdomen was opened found a par-ovarian cyst. Six months ago I removed a par-ovarian cyst which weighed fifty pounds. In this case I had made a diagnosis of ovarian tumor. Three months since I removed a twenty pound par-ovarian cyst from a girl eighteen years of age which I had diagnosed ovarian, and in several cases within the last two years I have found par-ovarian cysts where I have diagnosed ovarian tumors. On two or three occasions I have found large intra-ligamentous cysts, where I had diag-

nosed ovarian tumors. It is usually impossible to make a differential diagnosis between these cysts and the ordinary ovarian tumors until the abdomen is opened, nor is it important for they should all be removed.

In regard to fibroid tumors, I do not think we should be governed as much by the size of the tumor as by the symptoms. A tumor of considerable size may cause no symptoms that seriously interfere with the woman's health or happiness. A small fibroid may cause symptoms that demand removal of the tumor, and this should be our guide mainly in the extirpation of these tumors. I agree that fibroid tumors are frequently removed where there is no necessity for it; other operators may refuse to remove a fibroid when operation for its removal is imperatively demanded. I do not think anyone ought to undertake to do an hysterectomy who has not seen this work done and is thoroughly familiar with its technique, because while one hysterectomy may be a simple operation, the next may be one of the most difficult operations in abdominal surgery. To do this work a man should be a skillful operator, and should be prepared to treat any emergency or condition that may arise.

I have not had much experience in the removal of ovaries and tubes in the treatment of fibroid tumors. I remember one case upon which I so operated four years ago. The woman was suffering so much that something had to be done. The tubes were seven inches in length and large; the ovaries were four times the normal size but not cystic. She made an uninterrupted recovery, not only from the operation, but all symptoms were relieved. I saw the woman less than two months ago, and there had been no return of the symptoms; the tumor has decreased very much in size. I know of many cases where the tumors have decreased in size without treatment, and all symptoms have disappeared. I remember one case, the patient being the mother-in-law of a prominent lawyer of this city, who consulted me five years ago, and I recommended operation. She declined and went to Chicago and was treated by Dr. Martin, and while there was no immediate improvement, on her return to Louisville all the symptoms gradually disappeared and she is to-day apparently in perfect health, with the tumor very much decreased in size. So I repeat that it is not so much the size of the tumor that should govern us in our operations but the symptoms. As I remarked in presenting this specimen, concerning the three methods of treating the pedicle—the extra-peritoneal, intra-peritoneal and total extirpation. It depends upon the conditions that you have to deal with at the time, the fondness of the operator for one method over another and his expertness in doing the operation.

Dr. Cartledge spoke of ligating the arteries separately; that is a very good method, but I believe the operation can be done more rapidly and better by not doing so unless we do total extirpation. In the intra-pelvic but extra-peritoneal treatment of the pedicle the ligation of the uterine artery by including both layers of the broad ligament in the ligature will often bring peritoneal surface against peritoneal surface, thereby removing the necessity of suturing the flaps over the cervix. The fewer ligatures used in these cases the better.

Dr. J. W. Irwin: What percent of fibroid tumors are found maligant?

Dr. W. H. Wathen: It has not been proven that a fibroma has degenerated into a carcinoma, but its presence may constitute a *locus minoris resistentiæ* determining a local diathesis. With fibromata there is often a chronic glandular endometritis, which causes proliferation of the glands, at first typical, passing into the atypical or malignant. The round cell sarcoma may develop in the frame work of a fibroma and destroy the muscular fibres; and there may be a sarcomatous fibro-cyst—cancer may invade the uterus by the side of a fibroma; and cancer of the cervix is often associated with fibroma of the body.

Dr. A. M. Cartledge: I can hardly agree with Dr. McMurtry as to the incision: I believe the smaller the incision we make and yet allow thorough work the better. This applies to ovarian cysts as well as other abdominal tumors; it is possible to remove a very large cyst having several compartments, through a small incision. Of course we may go to the extreme in either direction, and I believe the incision should be governed entirely by the condition with which we have to deal, making it as small as consistent with thorough work. I do not mean to underestimate the importance of an incision suf-

ficiently large through which to work with ease, and where there are extensive adhesions the incision should be large enough to admit of thorough and perfect surgical work.

Dr. Wathen's point in regard to ligation is well taken except for one fact. We must remember that the greatest danger from hysterectomy is hemorrhage. While it may be true that the fewest possible number of ligatures should be inserted in the abdominal cavity, yet I believe his method of ligation is one of the bad points about his operation. In the enucleation of a fibroid tumor of the uterus we have the danger of hemorrhage from the ovarian and uterine arteries, which if it occurs may be very difficult to control. In forming the pedicle of such a tumor it is largely composed of muscular structures and great care should be taken in the ligation. I take the position that the arteries in this situation should be ligated separately, because if included with the pedicle or broad ligament, the liability of the ligature slipping owing to contraction of the muscular structures after the anæsthetic is eliminated, is very great. In separate ligation this danger is reduced to a minimum; when the ligature is applied direct to the uterine artery for instance it cannot slip, and therefore becomes perfectly safe.

DR. W. H. WATHEN: Dr. Cartledge is mistaken about the danger of the ligature slipping when passed through the peritoneal fold, because it is impossible for it to slip if applied in the manner I have suggested. The only danger is in failing to include the uterine artery in the ligature. If care is taken to include the artery, and the ligature is sufficiently strong it may easily be drawn tight enough to control hemorrhage. Dr. Cartledge magnifies the danger of hemorrhage after hysterectomy. Statistics show that there are very few recorded cases of fatal hemorrhage occurring after these operations, where the uterine arteries have been tied by any of the prevailing methods. Some fatal cases are reported, but most of them occurred years ago, and the fault was in the ligation of the pedicle itself composed of the neck of the womb, a method which no one would practice now because it is unreliable in controlling hemorrhage, and predisposes to sepsis by causing sloughing of the neck.

DR. A. M. CARTLEDGE: In the ligation of any blood vessel, it is important that the ligature be applied directly to the vessel; the more tissue included the greater the liability to hemorrhage.

DR. L. S. MCMURTRY: I am greatly pleased that the subject has received such marked attention and discussion by the Fellows of the Society. I have seen several cases of fibroma where hysterectomy was done several years after the appendages had been removed. At the hysterectomy the stumps where the appendages were removed showed that the operation had been thoroughly done, but the tumor had continued to grow. As a rule removal of the appendages in the early stage of fibroid growths of the uterus, is a very satisfactory operation. The appendages are nearly always found to be diseased. As stated in my opening remarks, and as has been demonstrated in the discussion, the great interest in the subject centers around the dangers of the operations, not from shock but from hemorrhage. I believe an investigation of the subject would show that a great many of the deaths following hysterectomy reported as resulting from shock, are really due to hemorrhage. If the abdomen were opened it would be discovered that bleeding had taken place from the stump treated intra-peritoneally. The stump of a fibroid tumor is composed of contractile muscular tissues, and is a very dangerous stump to leave in the pelvis. I have seen a number of cases in the practice of others where there has been an intra-peritoneal stump which was followed by serious trouble weeks afterward from abscess of the stump. After you tie the uterine arteries you cut off the greater part of the blood supply to the stump, and it is very liable to undergo necrotic changes.

One of the gentleman present has called my attention to the fact that in speaking of ovarian tumors I said nothing about tapping. The dangers of this procedure are so well known it is scarcely necessary to say anything about it. Invariably after tapping there will be more or less inflammation and adhesions.

The Advantages of Pental.

Phillips (Zeutsch. fur Kinder.), judging from an experience of 1,000 narcoses in the Kaiser Friedrick Hospital, Berlin, makes the following statements concerning the advantages of pental over chloroform.

(1) More rapid narcosis.
(2) Absence of or shorter period of excitement.
(3) Quick recovery.
(4) Absence of after effects such as are common with chloroform.
(5) Cyanosis rarely appears, and is then due to tonic contraction of diaphragm and glottis.

CURRENT LITERATURE REVIEWED.

IN CHARGE OF ELLISTON J. MORRIS, M. D., AND SAMUEL M. WILSON, M. D.

THE AMERICAN JOURNAL OF OBSTETRICS

For June contains a paper by Dr. George H. Rohe on

Hematoma of the Ovary.

The view that these are caused by an excessive hemorrhage into the Graafian follicle after rupture and escape of the ovule, seems to the author not tenable. The reasons given by him for rejecting this theory are that in many instances no rupture of the follicle has taken place. Besides, the corpus luteum frequently contains no blood. He believes that hematoma of the ovary, no matter how small, should be looked on as a pathological formation, having no essential connection with the process of ovulation. The cause he thinks is due to some nutritional change in the ovary or the blood vessels. The author does not look with favor on the conservative proceding of extirpating the hematoma and stitching up the wound in the ovary, but believes that the entire ovary should be removed, as he has always seen in these cases complications that require the removal of the ovary. He reports the case of a woman in the insane hospital in whom the removal of both appendages, one of which contained a hematoma and the other a cyst, resulted in complete restoration to health.

In conclusion he says: A hematoma may rupture and give rise to a pelvic hematocele. In other cases the bleeding may continue and the patient die of hemorrhage. The most serious danger from rupture is peritonitis or sepsis. The diagnosis of ovarian hematocele cannot be definitely made before abdominal section. Even when rupture occurs and a hematocele is formed the diagnosis rests between several conditions, often differentiated with difficulty, even after operation.

The only rational procedure is removal of the affected organ by abdominal section.

Dr. J. H. Carsten contributes a paper on

Cæsarean Section

in which he sums up his conclusions as follows:

1. In certain cases with an antero-posterior diameter of three inches craniotomy is justifiable.

2. With an antero-posterior diameter of less than three inches, Cæsarean section should be performed.

3. In the latter cases sometimes the classical; sometimes the Porro-Cæsarean section should be preferred.

Dr. J. E. Oldham discusses the subject of

Ectopic Gestation,

reporting several cases. The author favors the use of electricity. His manner of using galvanism was with a large clay electrode applied to the abdomen, and an ordinary vaginal electrode, wrapped with absorbent cotton, introduced into the vagina well under the tumor. The abdominal electrode was connected with the positive, and the vaginal electrode with the negative side of the battery.

In the first case reported, the course was so rapid that a positive diagnosis could not be made prior to the time of rupture, and that occuring into the peritoneal cavity, the hemorrhage was fatal. In the second case faradic electricity failed to destroy the vitality of the fetus, after a most thorough trial. In the third case galvanism used as stated did destroy the vitality of the fetus, and this case illustrates the fact the patients may conceive and bear children after the occurrence of ectopic gestation. The fourth case illustrates and bears out the statment of Pozzi that "internal suppuration may occur in the sac long after the contents have become encysted and rendered apparently an inert mass." The fifth case again demonstrates the efficiency of galvanism. In the sixth case galvanism was not effective, but whether on account of the intollerance of the patient to bear a current of sufficient strength, or whether from the advanced state of the pregnancy, the author is unable to say; he is inclined, however, to the former opinion.

Dr. Mary A. Dixon Jones contributes a paper on

The Minute Anatomy of the Fallopian Tubes,

suming up the result of her researches as follows:

1. In the tube-wall are six layers of smooth muscles. The two main layers are the circular and the longitudinal. These interlace, the circular has the broader area and is nearer the calibre; the longitudinal is nearer the peritoneum.

2. The inner surface of the tube-wall is made up of myxomatous or myxo-fibros connective tissue, which in turn is supplied with two muscle layers, a broader longitudinal and a narrow circular, both interlacing

3. The mucosa has folds with many ramifications, serving for the occlusion of the calibre during life. These folds are the result of alternate contractions and extensions of the two muscle-layers of the mucosa, the transverse and the longitudinal, which are visible throughout all the folds and all the ramifications, arranged in bundles close beneath the epithelial layer.

4. Outside of the longitudinal layer of the tube-wall is the layer of blood vessels, mainly, arteries and veins, in an arrangement similar to that known to exist in the walls of the uterus.

5. Beyond the vascular layers are the two narrow layers of smooth muscle fibres, both being oblique, both traceable from the uterine ostium up to the fimbriated extremity of the tube, and they correspond to the two oblique layers of the wall of the uterus. The two ob-

lique layers are bordered outwardly by the peritoneum, and seem to serve mainly for the regulation of the afflux of blood in the subjacent arteries and veins.

6. The circular and longitudinal muscle-layers are antagonistic in their action. If one layer is contracted, the other is relaxed. Again, the two muscle-layers of the tube-wall proper are antagonistic in their action to the muscles of the mucosa. The contraction of the muscles of the tube-wall is accompanied by a corresponding relaxation of the muscles of the mucosa. Within the folds the primary, secondary, and tertiary ramifications are produced by alternate contractions of smaller portions of the muscle-layers of the mucosa.

Dr. J. Foster Scott discusses

The Pathology and Treatment of Periuterine Pelvic Inflammations.

While it is pretty generally accepted now that the vast majority of periuterine pelvic inflamations (aside from those following puerperal septicemia) are caused by peritonitis consequent upon tubal disease. The author thinks that the condition of pelvic cellulitis will still continue to be a recognized pathological factor in cases of infection following upon childbirth, abortion, or the introduction of virulent poisons into wounds of the upper vagina, cervix, or uterus.

In the treatment of this condition the author advises, if the condition originates from a septic endometritis, that the uterus be curetted, washed out, and a gauze drain introduced up to the fundus. In the acute or chronic forms, where suppuration has not occured, the patient should be kept in bed at absolute rest, and have morning and evening hot douches, prolonged for fifteen to twenty minutes. If the bowels or not filled with impacted feces, the author thinks it advisable to keep the patient well under the influence of opiates to quiet peristaltic action. Painting over a large surface of the lower abdomen with iodine should be tried, and the author is in favor of the application of six or eight leeches to the portio vaginalis. Ice-cold applications he regards as better than hot poultices; the latter, in his estimation, favor the growth of septic organisms and hasten suppuration, which might be averted by cold. If there is a gonorrhœal history, the utmost trouble should be taken to prevent its ravages by antiseptics applied to the inner surfaces of the uterus, even if it has spread there. Diet and tonics are needed. Pain is to be met with morphia suppositories and opiates; and the temperature kept down by sponging with cold water and alcohol, and giving aconite and antipyretics with judgment. Celiotomy will be required if suppuration has occured, and in cases of tubercular peritonitis the abdomen should be opened and flushed with hot water freely.

The remaining papers in this issue are:

"Contributions to the Histology and Histogenesis of Sarcoma of the Uterus," by J. Whitridge Williams, M. D.

"An interesting Case of Vaginal Hysterectomy, with Remarks on Carcinoma Uteri," by Angus MacKinnon, M. D.

THE ANNALS OF GYNÆCOLOGY AND PÆDIATRY.

for June. Dr. Reuben Peterson contributes an article on

Strangulated Unbilical Hernia.

In regard to the determination of the amount of injury the bowel has received by the constriction, he suggests that the injured segment be enveloped in hot sponges, after releasing the constriction and drawing the bowel out through the incision, and any changes of color in the bowel well closely observed. It should not be decided too hastily that the injury has been permanent, and that an artificial anus must be made. Even should there be dark, necrotic spots remaining after the circulation has returned to the major portion of the affected part, it must be borne in mind that these may be only superficial, and the underlying layers unaffected. Except in extreme cases, he thinks, five or ten minutes can profitably be spent in waiting and observing the re-establishment of the circulation or its failures, the patient in the mean time being kept lightly under the anæsthetic.

In regard to what operative procedures should be adopted when the integrity of the bowel is impared, he is of the opinion that an artificial anus and a subsequent resection will probably give the best results in the hands of those unaccustomed to intestinal surgery. In regard to the prevention of the recurrence of a strangulated hernia, he gives preference to no one method of operating but whatever method he adopted, the endeavor must be to accurately approximate the fascia transversalis. If this be accomplished and the wound heal by first inprimary union, the chances are largely against a recurrence of the hernia.

Dr. Herman E. Hayd discusses the

Treatment of Tubal Disease,

giving as his opinion that in acute septic or gonorrhœal endo-salpingitis, the most radical measures must be resorted to early, as these inflammations so rapidly cause total destruction of the tubes and adjacent structures. Therefore dilatation and curettement and uterine drainage, as provided for by Polk's operation, is advised as cutting short the endometritis and aborting the possible salpingo-ovaritis, by preventing further spread of the infection. In the more chronic cases, where the tubes and ovaries are considerably involved, and their component elements thickened and perhaps cystic and filled with serum, blood or pus, salpingotomy or salpingo-oophorectomy is the only hope of relief. In a case with the history of a recent inflammation, with fixation of the uterus and a tender and painful mass on one or both sides of the pelvis, with some rise of temperature, the author advises an expectant plan of treatment. Rest; copious hot vaginal and rectal douches, if grateful and well borne, the inclined decubitus; a poultice to the lower abdomen if there be much pain; and later glycerin tampons, or 15 per cent. ichthyol and glycerin, or 50 per cent. boro glycerin. Painting the vault of the vagina every second or third day with

Churchill's tincture of iodine, or vaginal galvanism, and daily soluble movements from the bowels will often bring about resolution and absorption and a healthy restoration of the organs.

Appended to the paper is a table of operations performed by the author.

Dr. Augustus P. Clarke discusses the

Treatment of Fibromyoma of the Uterus.

The hemorrhage he states can often be kept under control by curetting the cavity of the uterus at intervals. Apostoli's method of galvanism will yield the best results in the interstitial variety on account of the contractions it produces in the fibrils of the muscular tissue of which these tumors are composed more than any other variety. The same is true of the subserous or subperitoneal variety. In tumors of slower growth, the employment of electrolysis may for a time be attended with seeming benefit, but it cannot be long continued without risk of exciting serious inflammation of the parametric tissue, or of superinducing or hastening a malignant degeneration. The removal of the appendages may be of material benefit, though this method does not produce as good results as are obtained by hysterectomy. Electricity should not be employed in tumors situated in the corporeal or fundal portion of the uterus, for later experiences show that the benefits to be derived by its use can best be had in those cases in which the tumor was originally interstitial, and from its position was made up of the muscular element, or was of a subserous or subperitoneal type, and had on account of the presence of an undue proportion of the muscular tissue taken on a rapid growth.

Dr. J. P. Elliott contributes a paper on

The Pathology of Pelvic Inflammation in Women,

in which he adopts the following classification of Dr. McMurtry:

1. Inflammation of the serous and cellular intrapelvic tissues cannot be separated clinically or histologically, hence they cannot be properly distinguished by the terms parametritis and perimatritis.

2. The pelvic cellulitis of Emmet, which corresponds to the peri uterine phlegmon of Nonat, is as rare as inflammation of the cellular tissue elsewhere.

3. Pelvic inflammation is, generally speaking, peritonitis resulting from disease of the ovaries or Fallopian tubes, or both.

4. Pelvic peritonitis presents every grade of activity, and is always symptomatic, never idiopathic.

We may name three general groups of these inflammations:

(*a*) Those of puerperal origin.

(*b*) Those of gonorrhœal origin.

(*c*) Those caused by infections carried to the endometrium by unclean instruments, tents, or medicinal agents, or those arising from traumatism.

The remaining paper in this issue is "The Indications for Cæsarean Section" by Dr. B. C. Hirst.

Among the editorials is a resume of the opinions of various authorities on the subject of castration in nervous diseases. The resume is prepared by Dr. Joseph Price.

IN THE SANITARIAN

for June appears an article by Dr. Charles Smart, U. S. Army, on

Drinking Water.

The lecturer stated that the main point or interest in regard to drinking water was the presence or absence of the germs of malaria, typhoid fever and cholera. When the germs of any one of these is present in water, there are also present certain organic compounds, as these germs generally enter water in sewage. It is for this reason that the chemist is appealed to to test for nitrogen compounds, etc., Inorganic salts are of course injurious if present in great quantity, but when that percentage is reached we can recognize their presence by taste.

Waters were classified as: rain or cistern waters, surface waters, subsoil or ground waters. Cistern water should be perefctly pure if moderate care is used in its collection and storage. Surface water is healthy or not according to the condition of the ground drained; but is so often unfit for use, that health officers generally condemn it.

The deep or subterranean waters are those that drain from high ground by sinking into the edges of a porus stratum underlying the clay of the bottom lands. When tapped by deep boring they are often found so full of mineral salts as to be unfit for use, but may be perfectly pure, such as that found in Memphis.

Statistics were given to show the comparative prevalence of typhoid fever in cities inversely proportional to the purity of their drinking water.

In the same number are articles by Dr. Samuel W. Abbott on "Recent Progress in Public Hygiene and Preventine Medicine;" by Dr. G. P. Coon, on "Needful Precautions Against the Spread of Communicable Diseases by Travel;" a suggestion that by means of a car or part of a car reserved for invalids, and built with special view to its being readily cleaned after use, the other passengers could be protected from contagion and a traveler need not go to his berth knowing that the last occupant had been a consumptive, or a convalescent from some infectious disease. "The berkshire Mills," by Dr. William Henry Thayer; "Sanitary Topography, Climate, and Mineral Springs of Maryland and Delaware," by Dr. A. U. Bell; "The Nation's Sin of Omission," by Dr. T. J. Bennett.

During the epidemic of cholera at Hamburg, Dr. N. Simmonds captured flies in a dissecting room where bodies were being examined and found numerous comma bacilli in them. It was ascertained that in one hour and a half these germs disappeared.

PERISCOPE.

IN CHARGE OF WM. E. PARKE, A.M., M. D.

THERAPEUTICS.

New Remedies of Last Year.

The following extract from *Treat's Medical Annual*, section of "Progress in Pharmacy," furnishes briefly some accurate facts on the latest new remedies.

Chloralose, a compound of glucose and chloral; recommended as a hypnotic, and favorably reported on after clinical trials by European and American investigators; has recently received a serious set-back, however, by adverse reports—including cases of poisoning.

Crystallin, a compound of either and methyl-alcohol, a substitute for collodium; the advantages claimed for it are, that it evaporates more slowly than collodium, forms a more durable and pliable or elastic covering, etc.

Di-iodform, a compound of carbon and iodine (about 96 per cent of latter); a new, odorless substitute for iodoform, non-irritating, and as good healing antiseptic as iodoform. Ferratin, presenting artifically the "iron component of animal food," a dietetic iron preparation from egg albumen and iron salts with the aid of alkalies; containing 7 per cent of iron; a brownish-red powder, almost odorless and tasteless. Easily assimilable, nourishing and strengthening, it is a food and blood tonic, highly recommended for anemia, chlorosis, loss of appetite, etc.

Sanguinal, another blood preparation, said to be a defibrinated, boiled- down blood with hemoglobin, consisting of 46 parts natural blood-salts, 10 parts oxyhemoglobin, and 44 parts peptonized muscle albumen; it can hardly be a savory morsel, and is dispensed in palatable tablets—for that reason, probably.

Somatose belongs in the same category; it is a nutritive product, 1 part representing 6 parts beef; occurs in granular powder form, easily soluble in water —so that it can be readily added to drink or food without patient's knowledge; is quickly absorbed, light on the stomach, and strengthens and nourishes the system naturally.

Abrastol is a new intestinal antiseptic, a sulphonated naphtol derivative.

Gallanol, a substitute for pyrogallol, is produced by boiling tannin and anilin oil together, with other manipulation. It is applied in eczemas, psoriasis and other skin affections; reports are favorable, and it has come into extended use in a surprisingly short time.

Formalin is a new disinfectant; a powerful bactericide, but comparatively non-toxic; safer to employ in ½ to 1 per cent solution than the usual to arbolic acid or sublimate solutions.

Thiosapol, new base for cosmetic and dermatological preparations; it is a sulfur compound of the same class as thiol; introduced in the form of creams, toilet soaps, etc.

Tetra-ethyl-ammonium has been introduced as a uric acid solvent, the discovery of this propertybeing the result of a systematic and extensive research at the Edison laboratory. Dr. Peterson, of New York, sponsored the new remedy, publishing a long climical report with most encouraging results and great promise; but no interest has been manifested in the matter by the profession generally.

Piperazin, the powerful uric acid solvent introduced a year before by Schering, has meanwhile become more popular and is now in extensive use here and in Europe. The therapeutic value of this remedy is now assured, and record of successful application is growing; and not only is applied for gout, rheumatism, gravel and other similar affections due to uric acid diathesis, but diabetes and other dieases are yielding to the influence of its solvent powders. Pharmacists should make a note of this correct dispensing method; piperazin-Schering, 10 grammes; water, 150 grammes. Make solution, and direct patient to dissolve a tablespoonful (10 grammes) each morning in a litre (quart) of water and drink during the day. That is the only correct dosage and method of exhibiting the drug.

Salipyrin, although several years old, has only been in use here during the past year; still, in this short time it has made good progress and is now in considerable use. A drawback to its success has been the practice in some places of trying to make salipyrin by simply mixing salicylic acid and antipyrin; this produces a mixture entirely different in physiological and therapeutical effects from the definite chemical compound. Salipyrin has found a wide field of application, as antipyretic, anti-rheumatic, analgesic (particularly in painful menstrual disorders), etc.; but its special recommendation has been as almost a specific for influenza, as a valuable aid in aborting incipient diphtheria, as a ready and effective remedy for simple coughs, colds, catarrhs, etc. The literature on salipyrin has accumulated rapidly during the past year, and all reports indicate that it is a most valuable agent.

MEDICINE.

Treatment of Red Nose.

Helbing (*Therap. Monatshefte*, January, 1894), calls attention to the treatment of red nose—a condition of little importance, it is true, but decidedly annoying to the possessor. The condition he refers to is the bluish-red color of some noses upon remaining for sometime in a warm room, coming in from the cold winter air, etc. The treatment he advises is the systematic application of the galvanic current. Both poles are applied to the nose and are continually moved about. The strength of the current he has regulated

by the amount of burning complained of by the patient. Five to eight elements of an ordinary battery suffice. If the patient is very sensitive, the anode may be applied to the zygoma and the nose gently stroked with the cathode. This application is followed by an intense redness of the skin, which lasts for an interval of two to forty-eight hours. Too strong currents must be avoided on account of excessive irritation they produce. The applications are repeated at intervals of two or three days. The method requires patience, and a considerable number applications (at least ten to fifteen), and the author has had to hold as many as thirty sittings. The author has used the method in thirty-one cases, and always with success, and gives report of two of the more obstinate cases.—*Cincin. Lancet-Clinic.*

Lithæmia.

On March 6th Professor DaCosta gave by invitation a lecture in the Medical Hall of the University of Pennsylvania on the Pathology of Lithæmia, and, taking this for a foundation, he indicated a line of treatment which, coming from such an authority, is worthy of full consideration. The term "lithæmia," as applied to a morbid state, involves much more than the presence in the blood of a mere excess of lithic or uric acid. Lithæmia is a modified from of gout, and appears to be the form in which gout particularly manifests itself in America; but in lithæmia deposits of urates in the vicinity of joints are not observed, and attacks of acute arthritis of toes and fingers do not occur. There may be, however, a painless enlargement of the terminal finger joints, especially in elderly people, with impairment of function. The cardiac hypertrophy and kidney degeneration of true gout do not belong to the clinical history of lithæmia. The blood tension may be increased, but it is so to a less degree than in gout, and the arteries do not exhibit the atheromatous condition that characterizes the graver form of the disorder. The spmptoms have already been described by the same authority. The main points are the impaired digestion, muscular pains, neuralgic attacks and pains in the tendons, indisposition to exertion, irritability of temper, depression of spirits, frequent and severe attacks of vertigo and migraine, sleeplessness, and drowiness during the day. The main factor in treatment is regulation of the diet. The food ought to be mainly vegetable. Green vegetables (especially asparagus), fresh fruits, stale or toasted bread, with the white mear of poultry and fish, should constitute the chief items. An excess of carbohydates, especially sugar, should be avoided. The only drink to be allowed is water, and sufficient quantities should be taken to flush the kidneys. Mineral waters may be ordered to accomplish the same purpose, Alcohol should be positively excluded. Exercise in the open air is also on important part of the treatment. But little drug treatment is required. Saline laxatives are very useful. A combination of lithium carbonate (2 gr,) with extract of nux vomica ($\frac{1}{8}$ gr,) given after meals is of special value. In attacks of lithæmic migraine a few doses of a mineral acid, it is claimed, will often cause the symptoms to disappear.—*Lancet.*

Physiology by Byron Robinson.

Few physicians realize the great usefulness of the omentum in abdominal surgery, except those who experiment on the abdominal viscera of animals or frequently open the human abdomen, The omentum is very small in infants according to my dissections. In adults it varies considerably. In some bodies we find it rolled and tucked up in one corner of the abdomen, especially if it contains but little fat. In most cadavers we find it covering the whole of the viscera below the the liver and stomach. In one body, Dr. Waite and myself post-mortemed last month, the heavy, thick omentum covered all the abdomen below the liver and stomach like a quilt tucked in around a bed. It almost equaled a second abdominal wall. It was a great and excellent protection of underlying viscera. The omentum is a double fold of peritoneum extending from the stomach to the colon. It generally descends into the pelvic cavity before it reflects to pass upon the abdomen to cover the colon. The uses of the omentum are: (a) it prevents the invasion of infection. As soon as infection gains entrance to the peritoneal cavity the omentum immediately circumscribes it. The omentum enables the inflammation to be coralled. Barriers are at once thrown out and the infectious, invader is checked. It quickly circumscribes perforated wounds of the intestines, appendix or other viscera. It is a kind of man-of-war, ready at all times to move on an infectious invader of the peritoneum. The omentum brooks no foreign invasion of infection. It assumes pleu-potentiary power over every peritoneal intruder and imprisons him early on the border. The omentum is the surgeon's best friend. It saves life of many a patient. (b) It prevents the adhesion of the intestines to the abdominal wall. It is common in autopsies to find the intestine adherent to the wall of the abdomen where the omentum accidentally happened to be absent. The adhesion of the intestine to any point is apt to destroy peristalsis and thus prevent the onward fæceal current. Nipping of the circumference of the gut from adhesions is just the same as Litter's hernia. (c) It heals wounds. I have shot many dogs and found in autopsies or in operating that the folds of the omentum had dropped into the wound and in many cases had completely healed it. The omentum has vital interests in the economy.

Nitrite of Amyl and Trinitrin in Hystero Epilepsy.

It is perhaps not out of place to call attention to a bit of recent experience with nitrite of amyl and nitro-glycerine in hystero-epilepsy

Case under consideration that of Laura W., was first seen with Dr. C. in February, 1891. It exhibited with classical precision the well-known striking features of the disease, consisting of a period of muscular tetanization, loss of consciousness, noisy respiration and deglutition, succeeded by the minor classical movements rapidly giving place to a series of exaggerated motions or contortions; body taking posture extreme opisthotonos, which would be exchanged for that of pleuros-thotonos with feet extended, toes pointed and distorted, displaying the *le pied bot hysterique* of Charcot. One attack would follow another with intervals of quiescence of variable length; consciousness would be restored and no complaint be made, except of severe pain in left ovary and left supra-mammary space. Pressure in either situation named had the effect of lessening or arresting the paroxysm, though the experiment of inducing their return by repeating the application was not tried for fear of provoked unfriendly comment.

Between February, 1891, and November, 1893, there occurred two slight attacks, the last of which was a single convulsion, and was due to an injury to the foot, caused by stepping on a nail. November 22, 1893, she was again seized; onset as violent in all its details as in first attack. She was found in extreme opisthotonos. Chloroform was administered, causing slight relaxation. It was repeated again and again without appreciable effect. A two-drop pearl of nitrite of amyl was crushed in the folds of a napkin and held to the nose. Almost immediately muscles rigid as iron bars relaxed, teeth and lips parted, arms fell limp by the sides, the body resumed a natural position bathed in profuse perspiration, and lastly the patient turned on her side and dropped into unbroken slumber, from which she did not awaken for many hours. In the next twenty-four hours there was no repetition, but at the end of that time there occurred the last of the series, which was easily controlled by a single two-drop pearl.

On the following day, and each day thereafter, she has received three doses of nitroglycerin of 1-250 of a grain each, tablet triturates of that strength being employed, which no doubt has kept off subsequent attacks. To date (Dec.8th) there has been no recurrence and none is expected, as she is able to be up all day and attend to light household duties, and complains less of suffering in ovary and breast, and says she feels much stronger and better in every way than during convalescence after any previous attack.—*R. B. Mc. Call, M. D., in American Theapist.*

SURGERY.

Intestinal Approximation.

In an article in the New York *Medical Record* on this subject, Dr. J. B. Murphy records a long number of cases and draws the following conclusions:

1. The more rapidly the operation is performed, the less the danger from shock.
2. The less the manipulation and exposure of the intestine, the less the danger of infection, post-operative paralysis, and adhesions.
3. The more uniform and continuous the pressure at approximation, the greater the assurance of adhesion and the less the liability of infiltration.
4. A line of approximation is as good as half an inch.
5. Mechanical means in the last five years have produced better results than the suture, in both lateral and end-to-end approximations.
6. The mortality in end-to-end approximations is much less than in lateral apposition, and should always be given the preference.
7. The more perfect the juxtaposition of the various layers, the less the interposition of fibrous tissue, and the more complete the regeneration across the line of union.
8. The juxtaposition of the similar histological layers of the wall of the intestine is an assurance against cicatricial contraction.
9. The more extensive the approximation surface, the larger the fibrous deposit, the greater the contraction.
10. The contraction with end-to-end is less than with lateral approximation.

An Italian physician says that strontium bromide is particularly valuable in gastric affections, especially acute catarrh, which, he says, show anew the remarkably favorable action of the drug. Carselli uses a syrup made by dissolving thirty grains of strontium bromide in a mixture of a fluid ounce of syrup of bitter orange peel and three fluid ounces and a half of distilled lettuce water. This amount is to be taken daily in three doses, during and after meals. It stops the vomiting and lessens pain. It is thought to act both directly upon the nervous system and as an antiseptic, arresting fermentation and thereby reducing the flatulent distension that gives rise to the pain.

ARMY AND NAVY.

CHANGES IN THE U. S. ARMY FROM JUNE 24 1894, to JULY 7, 1894.

Captain Louis S. Tesson, Assistant Surgeon, is relieved from dnty at Jefferson Barracks, Missouri, upon the arrival of Captain Charles B. Ewing, Assistant Surgeon, and ordered to duty as Attending Surgeon and Examiner of Recruits, Chicago, Ills., relieving Captain Daniel M. Appel, Assistant Surgeon.

Captain Appel on being thus relieved, ordered to Fort Porter, N. Y., for duty, relieving Major Curtis E. Price, Surgeon.

Major Price on being thus relieved is ordered to Fort Custer, Montana, for duty, re-

lieving Captain Peter R. Egan, Assistant Surgeon.

By direction of the President, the retirement from active service, June 13, 1894, of Colonel Bernard J. D. Irwin, Assistant Surgeon General, is announced.

Major George H. Torney, Surgeon, is relieved from duty as Attending Surgeon and Examiner of Recruits, at Philadelphia, Pa., and will report in person to the Superintendent U. S. Military Academy, West Point, N. Y., for duty at that post, relieving Major Philip F. Harvey, Surgeon, who after being thus relieved will report to the Commanding Officer, Plattsburg Barracks, N. Y., for duty at that post.

First Lieutenant Charles Wilcox, Assistant Surgeon, relieved from duty at Angel Island, Cal., and ordered to Presidio of San Francisco, Cal., for duty, relieving First Lieutenant Harlan E. McVay, Assistant Surgeon.

Lieutenant McVay, on being thus relieved, ordered to Alcatraz Island, Cal., for duty, relieving Captain Ogden Rafferty, Assistant Surgeon.

Captain Rafferty, on being thus relieved, ordered to Benicia Barracks, Cal., for duty, relieving Major Joseph B. Girard, Surgeon.

Major Girard on being thus relieved, ordered to duty at Presidio of San Francisco, Cal.

Lieutenant Colonel Johnson V. D. Middleton, Deputy Surgeon General, is relieved from duty at the Presidio of San Francisco, Cal., and will report to the Commanding General Department of California, for duty as Medical Director of that Department, relieving Lieutenant Colonel, Albert Hartsuff, Department Surgeon General.

Lieutenant Colonel Hartsuff on being thus relieved, will report in person to the Commanding General Department of the Missouri, for duty as Medical Director of that department.

Leave of absence for two months, to take effect upon the return of Major Calvin DeWitt, Surgeon to Fort Leavenworth, Kansas, is granted First Lieutenant William F. Lippitt, Jr., Assistant Surgeon.

Leave of absence for one month to take effect on or about the July 1st, 1894, is granted Captain Guy L. Edie, Assistant Snrgeon.

PROMOTIONS.

Lieutenant Colonel Joseph P. Wright, Deputy Surgeon General to be Assistant Surgeon General, with the rank of Colonel, May 16, 1894.

Major Alfred A. Woodhull, Surgeon, to be Deputy Surgeon General, with the rank of Lieutenant Colonel, May 16, 1894.

Major John S. Billings, Surgeon, to be Deputy Surgeon General, with the rank of Lieutenant Colonel, June 6, 1894.

Captain William R. Hall, Assistant Surgeon, to be Surgeon, with the rank of Major, May 16, 1894.

Captain George H. Torney, Assistant Surgeon, to be Surgeon, with the rank of Major, June 6, 1894.

NEWS AND MISCELLANY.

American Academy of Medicine.

XIXTH ANNUAL MEETING—PRELIMINARY NOTICE.

The XIXth Annual Meeting of the American Academy of Medicine will be held at the "Waumbek," Jefferson, N. H., on Wednesday and Thursday, August 29th and 30th, 1894. The greater part of the time is to be devoted to the discussion of certain problems relating to the Medico-social Relations of the Medical Profession to the "Dependent Classes." The following papers may be expected:

"The Retrogressives: What Produces Them; Classification." Bayard Holmes, Chicago, Ill.

"Importance of the Study of the Subject to the Profession." Charles McIntire, Easton, Pa.

"The Provident Dispensary in England." H. Webster Jones, London, England.

Title to be announced. J. A. Spalding, Portland, Me.

"Assistance and Care for the Blind." Charles A. Oliver, Philadelphia.

"Prevention of Blindness." Benjamin Lee, Philadelphia.

"Present Status of Legislation for the Prevention of Blindness from Infantile Ophthalmia." Lucien Howe, Buffalo.

"Senile Dementia and Testimentary Capacity." J. N. Whittaker, Cincinnati.

Title to be announced. Gershom H. Hill, Independence, Ia.

"What Agencies Conspire to Check Development in the minds of Children?" J. Madison Taylor, Philadelphia.

"The Medical Service of the U. S. Pension Bureau." P. S. Conner, Cincinnati.

"Physical Training for Delinquents." Helen C. Putnam, Providence, R. I.

"Government Commission instead of State License." J. D. Kelly, New Haven, Conn.

"The Relation of Food Adnlterations to the Dependent Classes." Henry Leffmann, Philadelphia.

Title to be announced. G. M. Gould, Philadelphia, President's Address.

Title to be announced. F. H. Gerrish, Portland, Me.

Several additional papers have been provisionally promised, if they can be read they will appear in the completed program.

Arrangements have been made for a special excursion from New York and Boston and return at reduced rates. A choice is offered of an eleven days excursion, including most of the expenses, or of returning immediately at the close of the meeting, and is open to any one desirous of attending the meeting, whether members of the Academy or not. Any additional information about the meeting or the excursion may be obtained from

CHARLES McINTIRE, *Secretary*,

ORIGINAL ARTICLES.

BACTERIOLOGY IN MIDWIFERY, AND PROPHYLAXIS OF PUERPERAL FEVERS.*

W. P. GAMBER. M. D., Stanton, Mich.

Each and every day brings the thoughtful and careful physician more and more to face the fact that the scientific world is still progressing, and he who keeps apace with the literature of medicine must acknowledge the fact, as proven by bacteriological investigations, that the various forms of micro-organisms are the prime factors in the causation of a large majority of the diseases in the human family. The last decade has shown, through the efforts of Pasteur, Koch, Sternberg, Vaughn, Welch and many others, wonderful progress in this branch of medical science. Many new truths have been discovered and there are still many more to be sought. The advancement already made makes it the duty of every physician to give more than ordinary attention to this subject. With our standard works on bacteriology and a good microscope, we are able in many cases to make an early and correct diagnosis. This is especially important in tuberculosis, in which it enables us to adopt early and efficient treatment,

While the minute details and the discovery of these micro-organisms are not essential for the successful practice of midwifery, yet I do claim that we should have a thorough knowledge of the nature of those germs which are instrumental in the causation of puerperal fevers.

There is a great plea for scientific obstetrics, but scientific obstetrics is not complete without a thorough knowledge of bacteriology.

Sternberg says:—"Recent researches indicate that infection by streptococcus pyogenes through the endometrium is the usual cause of *puerperal fever*. Thus Clivio and Monti demonstrated its presence in five cases of puerperal peritonitis. Czerniewski found it in the lochia of a large number of women suffering from puerperal fever, but in the lochia of fifty-seven healthy puerperal women he was able to find it only once. In ten fatal cases he found it in every instance, both in the lochial discharge during life and in the organs after death. Widal carefully studied a series of sixteen cases and arrived at the conclusion that this was the micro-organism in all. Bumm and other observers have given similar evidence. Eiselsberg and Emmerich have succeeded in demonstrating the presence of the streptococcus in hospital wards containing cases of erysipelas. That puerperal fever may result from infection through the accoucheur, when he has previously been in contact with cases of erysipelas, has long been taught, and, in view of the facts above recorded, is not difficult to understand. But in view of the fact that the streptococcus of pus has been found in vaginal mucus and in the buccal and nasal secretions of healthy persons, it may appear

*Read before the Michigan State Medical Society, May 1st, 1894.

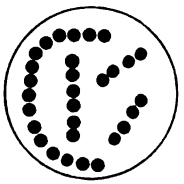
strange that more cases of puerperal fever not traceable to infection from erysipelas or from preceding cases do not occur more frequently. This is probably largely due to an attenuation of the pathogenic power of the streptococcus when it leads a saprophytic existence."

According to the teaching of Welch, which is in line with that of Sternberg, the class of micro-organisms chiefly concerned in the etiology of acute ulcerative endocarditis, meningitis, erysipelas, pyæmia, septicæmia, osteomyelitis, puerperal fevers, other septic and localized inflammatory affections and in general, the infection of wounds, embrace the somewhat heterogeneous group called pyogenic bacteria, of which the staphylococcus and streptococcus are the leading but not the sole representatives.

During the past three months I have made investigations in a number of healthy puerperal women, but was unable to find any of the pyogenic bacteria in the local discharge.

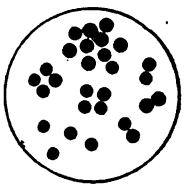
The fact that they are sometimes found in healthy puerperal woman does not prove that they are not the cause, for they are so widely distributed in nature, and found on healthy mucous membranes, waiting for some local lesion whereby they they may cause septic infection.

Fig. 1.



Streptococcus P.
Mag. 2000 Diam.

Fig. 2.



Staphylococcus.
Mag. 2000 Diam.

As these two micrococci, the streptococcus and staphylococcus, are often associated with each other and are similar in many respects, they will be considered in part together. They are both facultative parasites and are very common in suppurative processes generally. They are also common and widely distributed saprophytes which find the conditions necessary for their existence on the external surface of the human body, and of moist mucous membranes. They have been found upon the skin; in the secretions of the mouth, nose, and throat; in cultures from dirt beneath the fingernails of healthy persons; and in the dust of occupied apartments. Both of them grow, either in the presence or absence of oxygen, hence are called facultative anærobics. They stain readily with the basic aniline colors or methyl violet.

The steptococcus (Fig. 1) is the most important micro-organism under consideration. They are spherical in form, grow by binary division in one direction only, forming chains, and have a mean diameter of $\frac{1}{35000}$ of an inch. They multiply freely at ordinary room temperature, 60 to 70 degrees F., but more rapidly at blood heat. Thermal death-point, 130 degrees F. with ten minutes exposure. Its pecularity is to extend rapidly along the lymph spaces and lymphatic vessels, thus causing progressive phlegmonous inflammation.

According to recent investigations mecuric chloride solution, 1:2500, destroys vitality in two hours, and 1:30,000 restrains development; carbolic acid 1:300 destroys vitality in two hours, and 1:800 restrains development; creolin 1:130 destroys vitaity in two hours; and boracic acid solution 1:143 restrains development.

The staphylococcus aureus is shown in figure 2. They are spherical in form; with a mean diameter of $\frac{1}{35000}$ of an inch; are arranged singly, in pairs, in groups of four, and in irregular groups, and multiply rapidly at a temperature of 65 to 70 degrees F., but more rapidly at blood-heat. Thermal death-point, 140 degrees F. with ten minutes exposure.

This micrococcus differs from the streptococcus in the respect that it is not so apt to spread, but is found in furuncles, carbuncles, and various local abscesses; hence is the most common pyogenic micro-organism. Mercuric chloride solution, 1:2500, destroys vitality in two hours, and 1:80,000 restrains development; carbolic acid 1:125 destroys vitality in two hours, 1:800 restrains development; and boracic acid solution 1:30 destroys vitality in two hours, and 1:327 restrains development.

The staphylococcus has been considered, not because it is thought to be the cause of puerperal fever, but because of its similarity and intimate relation to the streptococcus; yet while the researches as given by Sternberg in his work on Bacteriology are still in line with the re-

searches of the present day, and the streptococcus pyogenes is still held to be the principle micro-organism causing puerperal fever, it is possible that the staphylococcus aureus has something to do with some of the milder cases of puerperal fever.

Experiments have shown that when the staphylococcus aureus is injected in sufficient quantity into the peritoneal cavity of some of the lower animals, it sets up fatal peritonitis, death taking place in a few days; and, what is true of this germ, is also true of the bacillus coli communis and the proteus vulgaris when they get into the peritoneal cavity, either from perforation of the bowels or some other source.

Good authority says that death may occur from the rapid absorption of a chemical poison developed in putrefying material, the decomposition of which is due to the "bacterium termo," and as this putrefying fluid is a good medium for the development of other life-destroying micro-organisms, the offensive odor should serve as a warning, in which case thorough antisepsis should be secured.

Lusk says: "In cases, however, where puerperal fever has a distinct period of invasion, and progresses step by step to a fatal ending, bacteria are always found invading the genital canal, and that the coexistence of blood-poison with the local lesion is an essential feature of puerperal fever." This lesion is usually of the endometrium, but it may be an abrasion of the vaginal mucous membrane, or a laceration of the cervix, and in rare cases they pass by the Fallopian tubes to the peritoneal cavity and excite salpingitis and peritonitis.

PROPHYLAXIS.

In the consideration of the prophylaxis of puerperal fever, we must realize the fact that the faithful practice of aseptic and antiseptic precautions greatly lightens the burden of responsibility that the practitioner of obstetrics must carry, yet his efforts are many times thwarted by ignorant and meddlesome persons.

We will discuss this part under three heads:

(1). Prevent the introduction of germs. —Different lying-in hospitals have adopted various sets of rules for the prevention of sepsis in the practice of midwifery.

The object of this paper is to give a few suggestions relative to the prevention of sepsis in private practice, as it differs very much from that which it is possible to carry out in hospitals. All agree that the attending physician should exercise the most scrupulous care in regard to personal cleanliness and disinfection, especially of hands, finger-nails, clothing and instruments. Before making a vaginal examination the hands and finger-nails should be well washed and scrubbed and then dipped in a solution of mercuric chloride 1:1000. The fingers should then be annointed with plain or camphorated vaseline. All instruments used should be thoroughly disinfected the same as before using them about a wound in surgery.

The use of the vaginal disinfectant douche at the onset of labor is still an unsettled question. Some use it and others do not. Should you arrive in time and wish to use it, first bathe the external genitals with a solution of mercuric chloride 1: 2000, then give the vaginal injection of a one to two per cent. solution of creolin, which is preferable to mercuric chloride for this purpose, as it is a lubricant as well as an antiseptic. Mercuric chloride is astringent and facilitates laceration. The vaginal douche of warm sterilized water continued daily during the last two months of gestation I believe to be beneficial, and I have never seen any ill effects from its use.

In regard to the use of the vaginal douche after labor, it is not approved of by a large number of physicians at the present day; but its use has strong followers on every hand. Galabin gives a simple post-partum irrigation of mercuric chloride 1: 3000, but during the entire puerperal period he uses two to two and one-half per cent. solution of carbolic acid. In uncomplicated, unprotracted cases of labor, the daily use of the douche of simple warm sterilized water is usually sufficient, provided the genitals are first bathed with sterilized water or some disinfectant solution, I believe that the thorough bathing of the lochial discharge from the genitals, at least twice a day, is of more importance than the vaginal douche. I have used this alone in several cases and find that when the bed-linen, clothing, etc., are unsoiled there is scarce-

ly any odor when at the bedside, and the patients seem to do as well as when both are used. I occasionlly find some difficulty in getting the average nurse to use the water in bathing the genitals, as some of them still think that not a drop of water must touch the patient until after the ninth day; but when you explain to the nurse its object, with instructions that they should be wiped thoroughly dry, your directions are usually followed. I find the absorbent pad for taking up the lochial discharge answers every purpose when made of several thicknesses of cheese-cloth which should be changed at least twice a day. Absorbent cotton may be inserted between the layers of the cheese-cloth.

The importance of good ventilation should not be forgotten, as it is a very efficient means of limiting the number of pyogenic bacteria and other noxious exhalations so common in occupied apartments. The lying-in room should be the largest and most pleasant in the house.

Good light is also beneficial. Day-light, and better still direct sunlight, is a powerful destroyer of many bacteria.

(2). Destroy the action of these germs. Remedial measures under this head will be considered in complicated cases, and when labor has been protracted, giving rise to probable laceration of the cervix, or of the vaginal mucous membrane; and, also, when the lochia becomes of an offensive odor after careful attention has been given to cleanliness and bathing the genitals. It is in these classes of cases that there is danger of sepsis, and in these the intra-vaginal douche should be used once or twice daily, as the case demands, of carbolic acid two per cent, or creolin two per cent; and, if mercuric chloride is used, it should be as strong as 1: 2000.

When these antiseptics are reduced materially in strength from that recommended, they fail to occomplish their purpose and merely act in partially washing away any micro-organisms that may be present and retarding the development for a time of those left *in situ*.

When the bad odor of the lochia is not controlled by using the douche, and it is found to come from the uterus, the advisability of using the curette and intra-uterine douche should be considered.

At the New York Post-Graduate School and Hospital they have adopted the following rules:

"An ante-operation douche should be given before any procedure, and an intra-uterine post-partum douche after instruments or hands have been in uterus, of carbolic acid three per cent. or creolin one per cent."

"Mercuric chloride 1: 1000 is used for hands and bathing genitals."

"N. B. No mercuric chloride is used in the parturient canal."

"No ante-partum nor post-partum douche shall be given without cause."

The strength as given by Sternberg of the following germicides may be used as a douche without doing harm to the vaginal mucous membrane: mercuric chloride, 1: 1000; carbolic acid, 1: 50; crelin, 1: 50; boracic acid, saturated solution.

(3). Shut up the doors—veins, lymphatics and Fallopian tubes. This is to be done by using suitable means for maintaining uterine contraction.

Lusk says: "In the peurperal period the warm carbolized douche stimulates uterine retraction."

While I do not think much of the binder for the purpose it is usually applied, it certainly gives comfort in many cases; and, when put on firmly for the first five to ten hours in cases of uterine inertia, it maintains intra-abdominal pressure, causes the after-pains to quiet down more readily, and is thought to prevent flooding. When this uterine inertia is due to depression of the vital forces, quinine, in moderate doses, becomes a valuable stimulant.

In the treatment of severe post-partum hemorrhage caused by uterine atony, the fundus should be pressed with one hand, with the other hand clear away all clots and give a hot intra-uterine douche. Ergotine may be given by hypodermatic injection.

I speak of these means of preventing the loss of blood because of its importance to the subject before us, as anæmia induced by hemorrhage is said to increase the susceptibility to septic infection, hence the loss of blood should be reduced to a minimum.

It has been my purpose in this paper to be as brief as possible in presenting the foregoing important measures, many of which may not be new, but if they are strictly followed in the management of obstetrical cases, the mortality may be reduced to a small percentage and the practice of midwifery be both easier and more successful.

THE THERAPEUTIC DIFFERENTIATIONS OF ACUTE AND CHRONIC DISEASES.

J. R. BLACK, M. D., NEWARK, OHIO.

A little over forty years ago, armed with the knowledge implied by a university medical degree, and fortified by the standard text books of the day, Watson, Wood, and the reference books of Copland, I started out in the avocation of trying to subdue disease. I can recall instances in my early efforts that brought me credit in the management of acute diseases, and not a very few humiliating defeats in the treatment of chronic ones. In some of the latter I was in not a few instances worsted by empirics, and by some nostrum remedies. Thinking that my diagnosis of the disorder must have been incorrect, a careful reading of authorities usually verified the accuracy of my diagnosis as well as the correctness of the treatment according to the standards. Finding that such an outcome in the treatment of chronic maladies by other physicians was by no means uncommon; that some skepticism of the healing art, and especially of scientific methods over empirical ones in lingering diseases, should have arisen, is what might be expected according to the ordinary rules of evidence. So a determination arose and became a ruling motive of my life to fathom the causes of the failures brought upon me by those whose knowledge of the elements of medicine, such as anatomy, physiology and pathology, were beneath contempt; and since that time a large part of my leisure hours has been devoted to the solution of the causes of my failures.

This led me into the study of etiology and hygiene, the latter a subject far too much over-looked by physicians in its bearings upon the production of disease and the restoration of health. Especially has a good conception of the first four laws of health enabled me to guide aright the sufferers from chronic maladies so that their health might be fully restored. For, bear in mind that the condition of the chronic invalid is not like that of one suffering by an acute disease; he is not confined to one room, or to indoor life; he takes his three meals a day more or less heartily; he is not kept between sheets day and night alike, but resumes his clothing each day; he is not deprived of exercise and the glorious light of sunshine like the acute sufferer in his darkened apartment.

In the management of acute diseases, both medical and lay attendants pay strict attention to the observance of a correct diet; very different is the ordinary routine during the treatment of a chronic derangement. If the victims have good appetites they are left pretty much to follow their discretion as to how much or what they ought to eat and drink; as to the manner and times of it, they are seldom thought of, much less mentioned.

Patients thus left to follow their own whims and caprices are allowed, while in a weak state, to try experiments on themselves, usually very painful ones, as to what is good for them, and what is not; information which the medical attendant should have furnished them in advance. Far too commonly the physicians' directions as to diet in chronic maladies are not specific, but vague and general, or are alluded to in a very languid and careless manner, so that the patients rightly conclude that very little importance is to be attached to them. Hence the observance of dietary rules, even in digestive derangements, is of the careless and fitful kind, and is apt to be worse in its selections than the physician intended. The inquiry often made of those who have long suffered under digestive and hepatic disorders in which a proper diet is often of supreme importance, as to what regulations the previous attendant had imposed, elicits the all but uniform response that they were told to be a little more careful than ordinary—whatever this may mean. Such an inculcation virtually concedes that the patient knows just about as much as the physician what is best for a sick man to eat, whether or not this be a slice or two of fried bacon, eaten with refined flour bread steaming hot from the oven, imperfectly masticated and hastened onward to the stomach with mouthfuls of tea or coffee, supplemented by a section or two of pie or of sweet cake at each meal.

Now as observation has made it clearly

apparent that the largest number of digestive and hepatic derangements are the products of errors in diet, it follows by the simplest rules of logic that if the cause be continuous, so also will be the effects. Yet in the face of this truism, many physicians only seek to remove a jarring dissonance in the machinery of life by the application of more and more medical oil, rather than by removing the cause on which dissonance depends.

The question of exercise is a very important one for those laboring under a chronic malady, as it involves the bringing to bear of a very active agent to restoration. Granting this is equivalent to admitting that the lines of treatment for this class of diseases are wholly different from and inapplicable to the acute.

The therapeutical benefit to be derived from regular exercise by those laboring under chronic maladies, seems to call for freshening up in the physicians mind, judging by the frequency of its neglect and the almost exclusive reliance on drugs to effect their removal. Nor is this mode of dealing with lingering diseases confined to a practitioner here and there. I have just looked into a standard text-book which is doubtless a guide to thousands, in which the nearest approach to recommending exercise as an aid to the cure of dyspepsia, is to travel. Much sounder was the advice of the celebrated Abernathy to a nobleman laboring under that ailment, "Earn a shilling a day and live on it." The cogency of this advice will be perceived when the effects of exercise are correctly pictured in the mind. It accelerates the circulation and nutrition of the tissues, enhances the building up of the new, and promotes the removal of the old and effete; thereby communicating renewed energy to all the functions, creating a desire for food with an ability to digest and assimilate and use it up morphologically. At the same time it exalts the functions of the nerve cells, gives impetus to the flow of this subtle force and begets the necessity, desire and certitude of good periodical rest and sleep.

Man draws his clothing and sustenance, not from his immediate surroundings alone, like the animal world, but from all the latitudes and longitudes of the earth, yet, although the wisest of all mundane beings and at the same time the most commanding and powerful, he is the sickliest of them all. And why? Simply because he neither knows or obeys the Ten Laws of Health. Barring inheritance and atavism, which can in time be obviated just as they can be originated when their productive factors are known, and accidents, of which the writer is a sample, all the disabilities ordinarily attributed to divine wrath, are avoidable, and they are not only avoidable but, with fewer exceptions than the fingers of a hand, curable.

I have often wondered at the skepticism of some physicians as to the power to cure. I know of no field equal to that of chronic maladies to convert unbelievers. Even the sources of fallacy that belong to the management of an acute disease are elimated in the chronic. The elements of the contest are simple, fair and open to no deceit or mistake. Here, for example, is the case of Mr. X., Y. or Z., plain to every eye-in open court so to speak. Dr. A, B, C and the vis medicatrix naturæ, after fair trials have failed to cure. The same person with the same disease is presented successively to each of these physicians as well as to the let alone method, and yet the lingering malady persists as before. But no sooner does Dr. D put his hand to the case than there is a prompt change for the better, which goes to complete and lasting success. Surely when this can be done, and is done for scores and hundreds of cases, all the needful evidence of ability to cure is furnished and which no one can decry or invalidate.

My old instructor, Professor Dickson, of the University of the City of New York, made a remark that I have often thought of, to-wit: "That acute diseases should be treated acutely, and chronic ones chronically." I know of no work nor any teacher of medicine that elaborates therapeutically and in detail, this injunction. More than ever am I daily assured of its truth and importance, and that the success that irregulars now and then attain to depends upon the use of remedies that do not overmuch disturb physiological function in the management of obstinate chronic maladies. Formerly it was a common query by applicants for treatment, "Doctor how long will you lay me up under your treatment before I can go about again?" My answer almost invariably is, "Not a day, but that day by day under the use of remedies that will

correct disordered functions, you will feel better and better until complete relief is afforded."

Very rarely it is needful in chronic affections to make use of what a distinguished Professor called the *lions* of the materia medica, but almost invariably of the *lambs*—gentle, but sufficient to bring an deficient function up to the healthy standard and held it there until sufficient tone and strength are acquired for the organ to run the function normally by itself. In the management of all chronic diseases it is seldom needful to disturb the healthy organs by strong medication, and never by remedies that will lurk in the system and produce as much harm, almost, as did the disease for which they were administered.

For nearly all lingering diseases the fluid or solid extracts are to be preferred, if prepared by a reliable pharmacist. If an habitual hepatic torpor and constipation is indicated, give euonymus or stillingia, combined, when the stomach is weak, with extract of gentian and Trommer's extract of malt, or, if of a neurasthenic type, with extract of celery or cypripedium. If mercurials are indicated only the mildest should be used, and then only for a short time and at bed time exclusively, with sufficient aloin to carry them off through the large intestine mildly on the ensuing morning.

In short, over medication is a crying evil in chronic ailments. The usual report of patients after such a course is that, "the medicine helped me, but soon after I was quite as bad as ever." By laying aside all the active armamentarium in the treatment of acute maladies, and resorting to the vegetable extracts that will mildly exalt depressed functions or check excessive ones, to bring them, in brief, and hold them for a time up to the healthy standard until sufficiently recovered to act for themselves, the work of curing chronic maladies will no longer be thrown into the hands of traveling empirics.

The differential I have to suggest in the treatment of acute diseases is that also of over-medication, or too large doses, and not frequently enough repeated. The dosometric system has much in it worthy of attention, and so far as my observation extends, it is decidedly favorable to it, having long ago written upon the subject of smaller doses and more frequently repeated ones.

In reference to chronic diseases, however, I can confidently aver that a reformation in practice is urgently called for. The abandonment of active remedies, with the calming effects of opiates or of spirituous drinks, and a due attention paid to the laws of health, will work cures where all before seemed hopeless and delusive. The treatment needs to be as chronic in some instances as to extend to a month or more, or at least until all signs of the disorder have disappeared. Of course there are a few diseases like confirmed tuberculosis, cancer and paralysis, that are not radically amenable to any remedies, but if due attention is given to the conditions of health, not fitfully but habitually, then attacks can with few exceptions be avoided. I firmly believe that by keeping all the organs of the body in a healthy state we have the surest of all guarantees that the attacks of microbes can be reduced to a very small degree. Like some others of the class protozoa they can only abide or thrive and multiply amid fouled, unhealthy or diseased tissues and secretions.

In conclusion I can not help remarking my belief that microbes are nearly always a condition and not a cause.

Infant Feeding.

An infant should double its weight in six months, and treble it in a year, if its nutrition is in every way satisfactory. The weighing and measuring should be conducted monthly, and the practical point is this: If a child does not increase at the rate of one pound a month during the first year of life, and twelve ounces a month during the second year, its nutrition is not satisfactory. If a child does not grow nearly three-quarters of an inch every month during the first year of life, and half an inch a month during the second year of life, it is not satisfactory. The latter is, of course, not of the same importance as the former. A nurse should cease nursing if the result does not come near to this proportion with regard to increase of weight. Clearly, premature children would not be so large, though they should increase at the same ratio.—Percy Boulton in *Brit. Med. Jour.*

COMMUNICATIONS.

CLINICAL NOTES ON THE THERAPEUTICAL APPLICATION OF STATIC ELECTRICITY.

G. FRANK LYDSTON, M.D.,* CHICAGO.

It has seemed to me that the knowledge of the usefulness of static electricity in medicine has been too closely restricted to the more advanced neurologists; indeed, I do not think that it is so universal even among them as its value justifies. A short clinical paper may therefore be suggestive to the general practitioner, in whose field of work the static current would seem to be of fully as great usefulness as in neurological practice. My attention was first called to the practical application of static electricity by the late Dr. Knight, for many years superintendent of the New York Hospital for Ruptured and Crippled. While sojourning in New York City, I had the opportunity of seeing a number of cases in which Dr. Knight and his talented assistant, Dr. Gibney—the present superintendent—had used the static current for the treatment of chronic joint affections. Dr. Knight, whose experience was certainly very large, was especially profuse in his praises of the static current. I saw the current applied in quite a number of cases of chronic rheumatic and inflammatory affections of the joints with seemingly excellent results. Pain, swelling and impairment of motion were rapidly improved. Local improvement of nutrition was in some cases apparently very rapid, even in joints that had been for a long timediseased. Since entering private practice, I have on numerous occasions had an opportunity of verifying the observations formerly made in hospital practice. I will acknowledge, however, that the results have by no means been so uniform nor as well marked as in the hospital for the ruptured and crippled, a fact which is very readily explained. The constant supervision of the hospital cases and the regulation of diet, the maintainance of rest and the application of massage and passive motion were of course more readily secured than in private practice. Until recently I was in the habit of prescribing static electricity and having it applied by others under my direction. It has seemed a much more reliable agent since I have personally applied it in my office practice. I have found the static current especially valuable in neurasthenia of various kinds, more particularly in those forms associated with brain fag and sexual hypochondriasis. The application of the static current to the spine has seemed to have a marked stimulating effect upon the genito-spinal center. It has been my observation that in neurasthenia the static current is especially valuable when applied after the general faradic bath. Some eleven years ago I was myself the subject of profound neurasthenia resulting from over-work and the exhaustion consequent upon a dissection wound. I at that time developed atrophic changes in the muscles of the hands, which were pronounced by Dr. Lyman and the late Dr. Jewell the beginning of progressive muscular atrophy. Associated with this condition was a decided tendency to melancholia and some slight paretic manifestations in the lower extremities. I also experienced frequent attacks of palpitation and cardiac dyspnœa. I began the use of the general faradic bath, but the result was apparently an increase of the condition of depression with which I was suffering. On combining the general faradic bath with the application of the static current to the spine I experienced a most exhilarating and tonic effect. When as a matter of convenience I stopped the general faradic bath, I found that I obtained very nearly the same effects from the static current alone. It was several years before I recovered the use of the muscles of the hands, and even now atrophic changes are apparent, but the neurasthenic symptoms from which I suffered improved rapidly and practically disappeared within two or three months after the beginning o the treatment.

I will take the liberty of briefly presenting a few cases in which static electricity has seemed to me to be of considerable value.

*Professor of the Surgical Diseases of the Genito-Urinary Organs and Syphilology in the College of Physicians and Surgeons; Surgeon to the Cook County Hospital.

CASE I. This case was that of a physician, 40 years of age, whose condition in many respects resembled my own as far as neurasthenia was concerned. The gentleman had been advised by several prominent physicians to change climate as he had a slight cough and tuberculosis was feared. Another well known-physician had stated in a very ambiguous way that the fault lay entirely with the gentleman's liver. Between these two opinions the changes had been rung upon a large variety of forms of neurasthenia. I found on investigation that the gentleman had been subjected to a great deal of worry incidental to a change of location and financial embarassment. This, associated with family troubles, irregularity of eating and insufficient sleep had produced neurasthenia associated with considerable digestive derangement. The tongue was heavily coated, the bowels constipated, the liver somewhat enlarged and tender. The lungs, as far as I could determine, were normal, and the urinary functions perfectly normal. I stopped the nervine tonics with which the patient was inundating himself and put him upon the general faradic bath. He, like myself, complained of the depressing effects of the bath until I added the application of the static current. He called at my office the day after the first application of the static current and said, "Doctor, ever since yesterday I feel as exhilarated as though I had drunk considerable champagne." This effect was maintained, and within six or eight weeks the doctor reported himself as perfectly well, having taken in the meantime no medicine whatever, save a saline in the morning from time to time, as required.

CASE II. A young lady, 16 years of age, was referred to me for lateral curvature of the spine. Electricity in various forms, massage, gymnastics and various appliances had been used with comparatively little effect. There appeared to be a marked general lack of tone associated with local muscular disturbance. The daily application of the static current to the spine and to the muscles of the affected side brought about rapid improvement, and while the deformity has never entirely disappeared, it is scarcely observable, and since a few months after beginning the use of static electricity, has been readily corrected by very light spinal support.

CASE III. A young lady was referred to me, complaining of palpitations, frequent flushings, severe headache, and a general feeling of weakness. The "hot flushes" as she expressed it, alternated with extreme coldness of the extremities. The pulse was 120 and somewhat irregular. Both Dr. Moyer and myself thought we detected from time to time a slight systolic bruit. The patient also had occasional attacks of gastralgia, and *suppressio mensium*, which lasted for six months. I could find absolutely no organic condition to account for her symptoms. She was to all appearances a buxom and healthy young woman, had plenty of color, and her general appearance was incompatible with some of the symptoms with which she complained. My colleague, Dr. Moyer, who saw the case with me, was equally at a loss to explain the symptoms present. Personally I suspected incipient Grave's disease, and in this Dr. Moyer coincided. The patient was under treatment for about four months without obtaining any relief. I then put her upon static electricity, using the wind current over the entire back and sparks to the spine. The patient was so sensitive at first that the treatment seemed very severe, but she soon became accustomed to the current and tolerated it fairly well. Within a month after beginning the treatment the menses reappeared, and began recurring every two weeks. They soon became quite profuse, which I considered an indication for the cessation of the static treatment. The menses then became regular with normal intervals. They have been since their reëstablishment, however, associated with some pain and considerable prostration for a few days. It might be well to state in this connection that careful examination failed to reveal any disease of the uterus or its adnexa. The patient was a *virgo intacta*. Under the static treatment the patient's general symptoms improved but slightly. Her headaches became especially severe, and the idea occurring to me that there might be a refractive error, I referred her to Dr. James A. Lydston for examination, with the result of discovering a considerable degree of astigmatism. This was corrected by a proper glass, and I have rarely seen so happy a creature as my patient has since

been. She appears at the present time perfectly well excepting at the menstrual epoch.

CASE IV.—A young man, 18 years of age, received some ten years ago a severe contusion of the hip with resulting osteoperosititis of the femur in the vicinity of the great trochanter. He had at times been quite lame and had suffered considerable pain and tenderness in the affected part. The patient had taken all kinds of treatment, but was averse to any operative procedures. I therefore began experimentally the use of the static current with the result of a marked amelioration of the symptoms. The enlargment of the bone at the site of the disease soon appreciably diminished. There is a question in my mind whether the application of electricity will be sufficiently efficacious to avoid the necessity of an operation. The amelioration has up to date been sufficiently marked to afford considerable encouragement in this class of cases.

CASE V.—A young man, 22 years of age, during the course of an acute gonorrhœa developed gonorrhœal arthritis of the right knee. This resulted in slight anchylosis, which was broken up from time to time, the usual application of passive motion being subsequently made. The joint remained stiff, tender and swollen for some time. Counter-irritation and various forms of internal medication were apparently of no service whatever; but under the daily use of the static current the condition rapidly improved, and within 8 or 10 weeks the patient was practically well. The patient claimed that he himself could see a marked improvement from day to day in the early part of the treatment.

CASE VI.—A gentleman, 45 years of age, consulted me regarding what to him was a very embarrassing predicament. He claimed that for some months his sexual vigor had been gradually deteriorating. Some three months before he consulted me, his wife had gone away upon a visit, and he improved the opportunity to indulge in all sorts of dissipation with the exception, strange to say, of sexual excess, which, however, he confessed he would have indulged in if he had the slightest inclination thereto. On the return of his wife several weeks before he saw me, he found he was absolutely incapable of fulfilling his marital duties, both from sexual indifference on his part and an actual lack of vigor. Under the use of the static current to the spine the patient rapidly improved, and within ten weeks was restored to his normal condition of virility.

CASE VII. A gentleman, 30 years of age, was referred to me by Dr. John Bartlett of Chicago. The patient complained that his sexual vigor had become impaired, and that for two months he had suffered with severe pains in the small of the back, which were greatly aggravated by sexual intercourse and by changes of weather. At times he found that he was unable to follow his vocation, that of a mason. I found that the patient had a narrow and irritable meatus and a stricture of large calibre at a depth of half an inch. The prostatic urethra was also exceedingly tender and irritable. I performed anterior urethrotomy and passed sounds every few days thereafter in the usual manner, but without any resulting improvement. The patient was begining to be rather discouraged, and I suggested the use of static electricity. The current was applied to the lumbo-sacral region, and in less than a week the pain had almost entirely disappeared. Within three weeks the patient reported himself as feeling perfectly well. He has remained free from pain for nearly three months, with the exception of one occasion, when he had been working very hard during damp weather. A single application of the static current again brought about complete relief. The sexual function has apparently been restored to its normal condition.

I have used the static current in a number of other cases with a greater or less degree of success. In some instances it has seemed to have no effect whatever. I have, however, seen no cases in which it seemed to be injurious, although my experience would lead me to believe that in some delicate and neurotic patients the agent should be used with a certain degree of circumspection.

I will frankly confess that my principal object in presenting this brief paper has been to bring out a thorough discussion of the limitations of static electricity by gentlemen who are much better qualified than myself to express opinions upon the subject.

DISEASE OF THE EAR AS A COMPLICATION IN EPIDEMIC INFLUENZA OR GRIPPE.

LAURENCE TURNBULL, M. D., PH. G.,* PHILADELPHIA, PA.

During the epidemic of influenz or a grippe in 1889-90, and 1891, we treated a large number of cases of ear disease both in the hospital and in private practice, and reported the same in the *Virginia Medical Journal.*

In most of the cases there was earache followed by acute otitis media, with a hemorrhagic inflammation of the membrana tympani, passing into perforations of the membrana tympani, the result of a micro-organism migrated from the naso-pharynx. In some of the cases there were double perforations with more or less reflex irritation of the brain, and some involvement of the mastoid, followed by tissue abscess situated just beneath the cortical layer. There was pain, chill, and more or less fever, followed by perforation of the membrana tympani; at first a mucous and, after a time, a discharge of pus. In almost all the cases there was a feeble circulation, irregular pulse and weak heart.

Instead of yielding promptly to the ordinary treatment by sterilized cleansing with a solution of biborate of soda and glycerine, cocaine solution at night to relieve pain, it had to be followed by carbolic acid with boric acid and aqua pura and careful inflating of the middle ear. Most of the recent cases were protracted for three, four, and even six weeks, and some longer. Then the apophysis of the mastoid became painful, and still more so on pressure. The insufflation of air diminishes the pain for a length of time but leaves the apophysis sensitive to touch, then we resort to the following prescription: Baths for the ear, of alcohol at 90 per cent. containing 20 grammes of pophyrised boric acid, or a super-saturated solution which Lowenberg introduced into use for the past twelve years with success in this class of cases.

In the adults there was a large loss of the membrana tympani of a pyriform shape. The nose, throat and Eustachian tubes were inflamed and irritated, requiring spraying with a solution of aqua hydrogentii deoxide 3 per cent. solution with half water, until all secretions were removed, while the pain was relieved by cocaine at night, and then toning the part with liquid albolene and menthol, equal parts, of this using 2 to 5 of the albolene. This treatment had a most happy effect upon the second stage of the rhinitis. Tonics had also to be freely administered. Simple elixir of U. S. P. with phosphate of iron and strychnia, omitting the quinia and substituting salacin. Salacin acts as a mild tonic reduces temperature, excites perspiration and relieves the catarrah and hyperæmia of the naso-pharyngeal mucous membrane. The quinia is apt to increase the tinnitus aurium which was one of the annoying symptoms.

Ever since 1891, there have been more or less sporadic cases as sequelæ of this distressing malady. In a case which we visited very recently in consultation, the daughter of a physician, a girl three years old, following an attack of grippe both ears discharged pus and both membranes were perforated. She was pale and feeble and had been in her room for three weeks. The posterior nares were so much affected that a young physician thought from the symptoms she had adenoids and proposed their removal. We found no indications of such growth, but irritation of the mucous membrane extending from the pharynx into the Eustachian tubes. This unfortunately had not been attended to and the tubes had not been kept free. This can so easily be done and should never be neglected, for by simply passing a short rubber tube of four or five inches, armed with a nozzle, into the nose and while the child cries, blow with the mouth piece, this will open the tube, which should be kept open every day after cleansing the nostrils and ears.

The child had no appetite for food and was weak. We therefore ordered esssence of beef and eggs soft boiled, as this latter is the only perfect food we have. The essence of beef acts as an admirable stimulant, using a quarter of a teaspoonful of "Armour's Extract" to a cup of warm

*Aural Surgeon to the Jefferson Medical College Hospital, etc.

water, adding a little salt to this makes a nice drink and few children will refuse it. We also ordered the wash before referred to, and the tonic. It is wonderful what large doses of strychnia can be given in these feeble conditions following grippe, so as to tone the heart and improve the appetite and digestion. This child was reported well after two weeks treatment.

CONCLUSIONS.

First. There is a peculiar inflammation of the ear termed influenzal otitis.

Second. It almost always commences with hemorrhagic, dark blue or black bullae seen in the lower posterior segment of the membrana tympani.

Third. After a time a perforation of the membrana tympani takes place with a discharge of bloody muco-serous fluid.

Fourth. The pain, which is severe before the perforation, is not entirely relieved by it and continues assuming more of a neuralgic character. There are subjective noises (tinnitus aurium) such as pounding, hammering and roaring, and if not properly treated by inflation or by Politzer's douche or the catheter, remain after all the inflammation has ceased.

Fifth. Fatal results may follow from meningitis, abscess of the brain, and more frequently sinus phlebitis. Such cases we are called upon to diagnose, being sent to our clinic as abscess of the brain.

CHRONIC MIDDLE EAR INFLAMMATION FOLLOWING INFLUENZA.

There is a class of cases in which the only indication of the effect on the ear is the intense otalgia; no perforation nor discharge. After three weeks or a month the patients present themselves with sunken membrana tympani, and a profound deafness. These cases are promptly improved by the use of the catheter and vapor of chloroform if it is in one ear; or if both are affected the use of Politzer's air bag charged with chloroform or ether, or equal parts of ether and tincture of iodine, a teaspoonful in a pint of hot water, to use in an inhaler; and a liniment of tincture capsici with iodine, to be applied to the mastoid process.

Several cases presented themselves last March, and this treatment with tonics have improved the hearing after each application, and when followed up restored it to its normal condition.

Common Mistakes of Doctors.

To promise a patient that you will cure him.

To promise that you can render more efficient service than your fellow-practitioner.

To promise that your pills are not bitter or the knife will not hurt.

To promise that the chill or fever will not rise so high to-morrow.

To allow your patient to dictate methods of treatment or remedies.

To allow yourself to be agitated by the criticisms or praises of the patient's friends.

To allow yourself to buoy up the patient when the case is hopeless.

To allow yourself to make a display of your intruments.

To allow yourself to experiment or exhibit your skill uncalled for.

To allow yourself by look or action in a consultation to show that you are displeased, and that if you had been called first matters would have been different.

To allow yourself to indulge in intoxicating beverages.

To allow yourself to rely wholly upon the subjective smyptoms for your diagnosis.—*Ohio Medical Journal.*

THE PLAGUE IN CHINA.—A terrible epidemic of the plague is now raging in China for the first time in eleven years. The disease is reported by medical observers to be very similar, if not identical with, the Great Plague of London in 1665; The disease appeared first in Canton the 1st of April, and spread with frightful rapidity among the poorer classes until the deaths had numbered many thousands. Some statements put the mortality at 60,000. About the 8th of June the disease appeared in Hong Kong, where it is now epidemic. At first only the natives were attacked, the mortality being about ninety per cent, but finally the European inhabitants have become victims to the disease, and several deaths have been reported. The daily death-rate in Hong Kong is nearly one hundred. In Canton the spread of the disease continues, but the morality is lessening.—*Boston Med. and Surgical Journal.*

LACERATION OF THE PERINEUM AND RECTO-VAGINAL FISTULA.*

E. E. MONTGOMERY, M. D.,† PHILADELPHIA, PA.

GENTLEMEN:—I bring a patient before you, who is 25 years of age and gives a good family history; her childhood was healthy and puberty occurred at 13; menstruation normal in time, lasted from five to eight days, was always very painful on the second day. She was married at 24, and had one child in July, '93. Labor was of long duration and completed with instruments. She has suffered since considerably from ventral hernia, due to separation of the recti muscles, permitting a protrusion as large as two fists above the umbilicus. She complains of pelvic weight and of dull pain in the pelvis and down the limbs, and has to take frequent rest. Her bowels are constipated, requiring the use of purgatives. During the evacuation of the bowels a small quantity of fecal matter passes into the vagina. The urine is negative.

Examining this patient, we find evidence of laceration of the perineum, the repair of which has been attempted but was incomplete, as an opening remains communicating with the rectum. This communication is above the sphincter, so that the discharge occurs into the vagina. This is naturally a source of great discomfort to the patient, although the opening is very small. We propose to operate to-day for the purpose, first of closing the opening, and second, to repair the perineum, and having dissected up the flap through the point at which the fistula opens, we will close the opening with buried sutures, then introduce sutures to build up the perineum. In this way we feel sure both conditions will be relieved.

To add to the complications we find this patient has a retroverted uterus, which is very painful to the touch and is bound down by adhesions. If we are unable to overcome this while the patient is under the anæsthetic, we will possibly follow the perineal operation by opening the abdomen, tearing up adhesions, fix the uterus forward, and thus correct the displacement, although it will require a somewhat complicated operation, or rather a series of operations, to do so. It is much better, however, to do the entire amount of operating necessary to correct the condition at the one sitting, rather than to have her look forward to a second siege. With many patients it is a great tax upon time and strength where the means of the patient are limited, to feel that it is necessary to undergo two operations. Neither operation is so critical but what the patient will be able to endure all at the same time.

As a preliminary to all plastic operations we have the vagina thoroughly cleaned, the bowels evacuated in order to remove any scybalous masses that might cause interference with union. The vagina will be cleaned by scrubbing with a solution of creolin and soap in order to remove any material that might possibly infect the wound. The superfluous material will be washed away with sterilized water.

After having placed the patient under an anæsthetic, careful examination is made to ascertain whether it would be necessary to resort to abdominal operation, but by manipulation it is discovered that the uterus can be loosened and a section will be unnecessary. No enlargement of either ovaries or tubes was discovered so that all that was left to do was the plastic operation upon the perineum. Now as you were informed earlier, this fistulous opening projects from just above the sphincter and into the vagina. The perineum, as reconstructed, is defective, so that instead of denuding the surface for a new perineum, we will proceed to split the structure that remains, dissecting the flap upward and carrying it well above the fistulous opening. As the flap is lifted up the incision presents a somewhat crescent shape appearance. Lifting this up, sponging out the parts carefully, I then introduce a suture of kangaroo tendon on either side of the small opening; tying these the opening is secured closely. Sutures are then introduced from side to side, bringing the de-

*Clinical Lecture Delivered at the Jefferson Hospital, March 20, 1894.

†Professor of Clinical Gynecology, Jefferson Medical College; Gynecologist to Jefferson and St. Joseph's Hospitals; Obstetrician to Philadelphia Hospital; President of Alumni Association, Jefferson Medical College.

nuded surfaces in apposition, pushing forward the flap to form the posterior wall of the vagina. As the parts are brought in apposition, taking care to sponge out the cavity and remove all blood clots, you see the perineum is again built up, making a good support to the pelvic floor.

The subject of laceration of the perineum is of very great practical interest for the reason that it probably occurs more frequently than any other lesion of the genital tract. It is a lesion that occurs in spite of every precaution that can be exercised, in about 15 per cent. of patients who come to labor for the first time. The conditions which cause laceration of the perineum, are faulty development of the individual; thus, the curve of the sacrum is very marked, or on the contrary, may be slight. In either condition the danger of rupture of the perineum will be increased. The perineum is long, the vulva small, perineum rigid, or the patient may have a large amount of adipose tissue, all of which causes increase the danger of laceration. These are conditions in which the individual is at fault. Then we may have a disproportionate size of the head of the fetus, or it may occupy an abnormal position which increases the amount of tension upon the perineum; occipito-posterior positions or where the head fails to rotate, are causes which increase the danger of the lesion. Then the fetus may have a large head from hydrocephalus. Premature efforts made at delivery of the patient, high application of the forceps, attempts at version, may result in laceration.

The treatment of such a lesion will necessarily depend upon the condition of the individual. Your professor of obstetrics will tell you that in every case in which it is possible, the perineum should be subjected to an immediate repair in order to avoid the suffering to the patient from a defective pelvic floor and the inconvenience of a secondary operation. It should not be forgotten, however, that there are some cases in which an immediate operation would be unjustifiable or unpromising. In those cases in which the woman has been subjected to long duration of labor, where it has been necessary to resort to manual or instrumental interference, the tissues have been very much bruised and lacerated; in such cases the early union would endanger the patient from the defective drainage and the probability of locking up material which would result from sloughing tissues. Even in these cases, however, where laceration has extended into the recto-vaginal septum, sutures may be introduced in such a way as to restore the septum and give control of the sphincter so that a subsequent secondary operation will be much less difficult, and the patient will not experience the great inconvenience until the parts are in such a condition as to permit of their complete repair. The cases in which laceration of the perineum is complete and has extended into the recto-vaginal septum are those which present the greatest difficulty in securing the proper apposition and restoration of the function of the sphincter. Not unfrequently do we see cases in which the perineum seem to be normal in length, but the patient complains of want of control of the sphincter muscle so that she is unable subsequently to avoid the discomfort of the escape of either flatus or liquid feces. In every operation of complete laceration of the spincter, the first object of repair should be the restoration of the function of the spincter as that which gives the patient the greatest inconvenience, and the second the restoration of the perineum.

When we come to the consideration of the treatment of laceration of the perineum the method by which the laceration should be repaired must be dependent upon the particular lesion. You hear of the flap operation, the various methods of denudation and the marked advantages of this and that procedure, but I wish to impress upon you that there is no single operation that is applicable to every individual. The operator should have sufficient ingenuity to fit the procedure to the individual case, and not the case to the operation. You should endeavor to study the necessity and conditions in the case before you, and do such an operation as will insure the most thorough repair and place the patient in the condition nearest that which she had prior to its occurrence. I have repeatedly performed before you various operative procedures, so I will not enter into their further discussion at this time.

I propose to speak of the conditions in this individual besides the laceration of the

perineum, and that is, particularly, the presence of the recto-vaginal fistula. Fistulæ are not infrequent in women as a result of lesions that occur during labor. Possibly laceration may take place through the vaginal septum and in the union of the parts a fissure will remain. Possibly a portion of the septum may be subjected to long continued pressure, which has occasioned a loss of its vitality and it has subsequently sloughed, resulting in a fistula. The discomfort of the patient will depend largely upon the size of the fistulous opening. Thus, where large, fecal matter will continually pass through, being a source of great mortification to the patient and her family. In every recto-vaginal fistula, however, it is important that careful examination should be made of the rectum, for not unfrequently such fistulæ exist as the result of malignant disease in the bowel. A stricture is formed, ulceration takes place above it and gradually opens into the vagina, in some cases the entire contents of the bowel passing through this canal. In a case which came under my observation recently, a woman was sent to me suffering from a large ovarian tumor, such a case as I would without question have advised to submit to an operation for the removal of the growth; but in making careful examination of the case, introducing the finger into the vagina, I found evidence of the presence of fecal matter, and a large opening existed through the recto-vaginal septum. Introducing the finger into the rectum, it was evident that the gut for some considerable extent was the seat of malignant disease to such a degree that it was utterly impossible to hope by an operative procedure to remove it. Under such circumstances, there was nothing for me to do but leave the patient to bear her burden. Sometimes these fistulæ may result from the presence of an abscess in the wall of the rectum, from a suppurating hemorrhoid, or traumatism, so that a small fistulous opening is present.

There are various methods by which such openings may be treated; simply denuding the vaginal surfaces would not be sufficient. If we have a small opening, the better precedure would be to dissect up a flap, as we have done in this case, close the opening by buried sutures and then stitch over it the flap. A vertical incision may be made directly through the opening, dissecting a flap upon either side, introducing the buried sutures, stitching the vaginal flaps over it. This method of treating the case accomplishes giving as little pressure upon the parts as is possible. The buried suture may consist of kangaroo tendon, small catgut or fine silk, using preferably that which is used for operations upon the eye. If this is carefully disinfected by heat, and care is exercised in its introduction, it gives no inconvenience. In some cases where the introduction of the sutures leaves a gaping opening in the rectum, it would be better to introduce sutures in the rectal mucous membrane in such a way as to hold the surfaces in contact to prevent the soiling of the wound until the union has taken place. As we have closed the fistulous opening in the patient upon whom we have operated this morning, and restored the perineum, I do not have the slightest fear of any redevelopment.

I feel that in this patient we have been also fortunate in being able to avoid the necessity of doing an abdominal operation; in other words, to bring about the correction of the displacement without the necessity of subjecting her to abdominal section. The correction of such displacements in all such conditions, is exceedingly important, as where the uterus is retroverted, presses upon the rectum, it gives rise to a congestion of the lower vessels of this organ, particularly where the stump is heavy, producing probability of delay in union, and even not only failure to unite, but sometimes, through the ulcerative process, increases the size of the opening, so that I make it a rule never to perform an operation upon the rectum until I make sure that the rectal disease is not a result of some malposition or enlargement of the uterus.

EDITORIAL.

ERRORS OF MEDICAL WRITERS.

Some time ago we read in a religious weekly, which is ably conducted, the assertion that Fielding in one of his novels had spoken of an insane asylum, one of the inmates of which was trying to extract sunbeams from cucumbers. Two great errors were committed by the writer, errors which our readers so readily recognize it is unnecessary to point them out. The writer was a very scholarly man, his life chiefly spent among books, and his making such mistakes would therefore seem highly improbable.

Corresponding errors are not uncommon on the part of medical writers. Errors as to dates, as to persons, and as to priority; one form of the latter is claiming as original that which was done by another years before. Now in regard to the last topic, undoubtedly truths and methods of practice may be re-discovered, for as one of the great philosophic writers has said, "Novelty is only oblivion." Yet in other instances the author has read, or been told that another has said, or devised this or that; the]s go by, and the information has faded from his consciousness, but the fact without its source revives in such a way that it seems an original conception. and so he publishes it. We purposely omit in our consideration those depraved creatures who deliberately steal another's invention, proclaiming it as their own, and who deserve nothing but general professional contempt; they are as bad as the doctors who steal patients, or slander fellow members of the profession, and like them should be sent to Conventry, since there is no penitentiary provided for such culprits.

The errors we shall consider may not involve any great culpability, but still they can hardly be called venial, for a man who assumes the responsibility of teaching the profession ought not to be careless as to dates or persons, and ought to be accurate in his statements when, by careful research, accuracy is possible.

We shall point out some of these errors, chiefly for a reason similar to that given in former times by an English judge, when sentencing a horse-thief, "You are hung, not for stealing a horse, but in order that horses may not be stolen." In an excellent and well-known work upon Obstetrics we read: "Wallace praises vinegar as a certain and safe remedy for *post-partum* hemorrhage." Reference is made to the third volume of the Transactions of the American Gynecological Society. The reader in turning to this volume, will find that the late Dr. Wallace did not "praise vinegar," but this commendation was given in an admirable practical paper upon *post-partum* hemorrhage by Dr. Penrose. In the same work Leyman is referred to in connection with an extraordinary knot of the umbilical cord. Now in some French works the name is given thus, but if the original paper by Read, (*American Journal of the Medical Sciences*, 1861,) be consulted it will be found that the case was reported by the late Dr. George H. Lyman of Boston. We would not refer to these instances if in a review of a preceding edition the errors had not been pointed out; probably the author did not see the review, or seeing it, did not think the errors important enough to correct.

Within the last few years there have been papers in medical journals advocating the application of moist sponge and compression in the treatment of mammary abscess. Before these articles appeared the second edition of Gross's *Surgery* was published, 1862, and in it the following passage, relating to mammary abscess, is found: "Within the last few years, a more scientific mode of management has been extensively pursued in this country, in consequence of the recommendation of Dr. Foster. It consists simply in the application of compressed sponge," etc. The compressed sponge was applied after the abscess was opened and the breast covered with cotton batting; then a bandage was neatly adjusted, and from time to time water put upon the bandage, and of course the sponge thus became swelled, making equal and gentle pressure upon the organ, securing the apposition of the walls of the suppurating cavities, and thus union more promptly than by other methods of treatment. Many American practitioners were employing this method of sponge-treatment more than thirty years ago: but some recent writers seem not to have learned it.

In 1859, Dr. Paul De Lacy Baker, of Eufaula, Alabama, first used veratrum viride in the treatment of puerperal eclampsia as may be seen by referring to the *Southern Medical and Surgical Journal*, September, 1859. But in a recent paper in the Transactions of the American Gynecological Society, it is stated that the first employment of the remedy for this purpose was by a Brooklyn doctor, giving a date some years after Dr. Baker's use of the agent.

A few months ago a practitioner of recognized ability, proposed the use of a French toy balloon for exposure of the fistulous margins in operating for vesico-vaginal fistula. But Foucher (*Gazette des Hopitaux*, 1862,) had anticipated him more than thirty years. The method of Foucher is referred to in the important volume of Deroubaix, *Traite des Fistules uro-genitales de la femme*, 1870. The only difference is that the Frenchman filled the rubber reservoir with air, while the American employs warm sterilized water or Thiersch's solution.

We might continue our list for some time, but it seems unnecessary. If this exposure shall have any good effect in lessening carelessness on the part of medical authors, and encouraging literary research in professional subjects upon their part, its object will be accomplished; its only purpose is, referring to the illustration given to prevent horses from being stolen.

ABSTRACTS.

POSTERIOR URETHRITIS.

Dr. F. Tilden Brown, in a paper with this title, says: Acute posterior urethritis rather a complication than a sequence of anterior urethritis. Some think that the anto-infective agent of gonorrhœa is conveyed from the anterior to the posterior urethra, and other portions by means of the lymph channels. Most observers, however,are inclined to believe that the disease traverses to the posterior urethra by continuity. At any rate, between the 16th and 26th day, an extension generally takes place to the posterior urethra. When the bulbous urethra is filled with pus there may be pressure upon it, by the clothes or otherwise, which favors its continuance. Locomotive engineers, tailors, oarsmen and bicyclists seem particularly prone to this complication. The paucity of glands, lacunæ and follicles in the porterior urethra, as compared with the anterior urethra, seems to offer the best explanation of its frequently escaping infection. He had seen several cases in which the fluid has passed into the bladder during irrigation of the urethra with a Kiefer nozzle. Spontaneous extension of an anterior urethritis to the posterior uretha may be expected in a debilitated person. The subjective symptoms may be at first wanting, and hence the condition may for a time be overlooked, and not be discovered until after the patient again indulges in sexual intercourse, when the sudden reappearance of the discharge may lead him to think that he has suffered a new infection. There is, however, more commonly a sudden development of dysuria and disturbance of the sexual apparatus. Tenesmus is the all-important symptom in posterior urethritis, and there will be urgent demand to urinate, which, if not immediately attended to, will lead to a dribbling of the urine. Spermatozoa may be present with undue frequency in the urine, and lead to a suspicion of the existence of a posterior urethritis. In acute posterior urethritis, instrumental examination is contraindicated. By rectal examination by the finger, it will be found that pressure upon the prostate gland will cause pain and tenesmus. When the affection is severe there may be marked constitutional symptoms. Unless the disease be carefully and systematically treated, there will be frequent relapses. In the treatment the tenesmus must first be relived by the use of suppositories or deep injections of cocaine or morphine. The urine should be rendered nearly neutral, using the benzoate of ammonia when the urine is alkaline, or the bitartrate of potash when the urine is acid. Sandal-wood or salol may be administered internally. After the subsidence of the acute symptoms, deep urethral injections of very weak solutions of nitrate of silver may be employed. In chronic posterior urethritis the amount of disturbance is quite variable. In what proportion of cases the gonococci cease to exist is not known, but all such cases should be looked upon as suspicious. To determine whether or not a case is still capable of carrying infection, it may be necessary to produce an exacerbation of the disease by the introduction of an irritating solution, for it is well known that gonococci are much more numerous during such an exacerbation. The subjective symptoms are similar to those of the acute form, except that tenesmus is usually absent. The existence of the "comma" thread in the second urine glass is strongly suggestive of chronic disease of the posterior urethra if disease of the anterior urethra can be excluded. If disease of the anterior urethra cannot be excluded, this portion of the canal should be thoroughly irrigated, then the first passage of urine would indicate the condition of the posterior urethra. Deep pressure over the membranous urethra and perineum is more likely to show tenderness than digitali examination of the rectum. Here the urethoscope is exceedingly valuable. At the first examination the lesion is exposed, and a 3-per-cent. solution of nitrate of silver applied by means of a specially devised syringe with a cotton tip. This treatment should usually be repeated after two or three days. When the submucous layers are infiltrated, absorption will be promoted and better results obtained by the use of iodine.—*Jour. Cut. and Genito-uri. Dis.*

THE INTERNATIONAL SANITARY CONFERENCE OF PARIS.

The International Sanitary Conference of Paris, which has just closed a two month's session, marks another advance in the progress of state medicine. This was the seventh similar conference, but the results of its work are to prove far more important than any of its predecessors While other conferences have con.idered questions more immediately relating to cholera in Western Asia and Eastern Europe, this Conference grappled with the more difficult subject of preventing the transportation of the cholera infection from India by the pilgrims to Mecca.

This problem is beset with difficulties from whatever side it is approached. On the one hand are the religious superstitions of the Musselmans that render them intolerant of any control; on the other are the jealousies of local governments, which make them resent any interference with their subjects by other powers, and, finally, there are innumerable complications arising from European territorial and commerical interests. It appears, however, that the Conference was able to solve all of these perplexing difficulties, and formulate an international series of regulations upon which the states represented will finally be able to unite.

Great credit is due the French Government for its persistent effort to secure international co-operation in the prevention of the spread of cholera. It called the first Conference as early as 1851, for the purpose of securing a uniform system of quarantine, but the results were not attained. In 1859 it attempted to secure a Conference, but the draft of the convention was not acceded to. In 1866 it succeeded in having a Conference of all the States of Europe, Egypt and Persia, at Constantinople, where many of the questions relating to an international agreement on methods of preventing cholera were discussed. But the time had not arrived for the adoption of the regulations proposed, and the Conference failed of immediate results. But it is apparent that there was a much nearer approach to an agreement than heretofore. Three Conferences have since been held, viz., at Rome, Venice, and Dresden, all of which resulted in agreements as to the methods of dealing with cholera in Europe. Finally, the Government of France called the present Conference, and its programme brought prominently forward the question of an international agreement on regulations governing the pilgrimages to Mecca.

The results arrived at were the adoption of regulations which place the pilgrim under strict sanitary care from his departure to his return home. He must first secure a sanitary passport from the local authority, giving full details as to his person and locality; at the port of departure he must be detained for cleansing and disinfection; he can embark only on pilgrim ships; these ships must have a qualified physician, ample space, pure water, good food, a disinfecting apparatus hospital accommodations, etc. ; island stations are provided, having every necessary appliance for cleansing and disinfection, where the pilgrims debark and undergo cleansing, as also the ship. At Mecca the pilgrim is under rigid surveillance, and on his return receives another passport stating his condition. The code of regulations is very minute, and if they are enforced in good faith would seem to render it impossible for cholera again to spread from India along the routes of the pilgrimages as heretofore.

We learn that the delegates from the United States endeavored to have the delegates from the Conference add to its programme the closely allied subject of the prevention of the spread of cholera by emigrants from Europe to the United States. The suggestion was favorably received by the Conference, but as the delegations were selected for the express purpose of considering the pilgrimages of the Musselmans, it was decided to postpone the emigrant question to a future Conference. It is greatly to be regretted that this Conference could not have included the emigrant with the pilgrim, for the larger number of the regulations made for the latter would apply to the former. Every emigrant from Europe to the United States ought to be required to obtain a sanitary passport from the local authority, setting forth the health of the locality and other details as to the cleanliness of his personal effects, freedom from all forms of infection, etc. Without this passport he should not be allowed to embark for this country. At the port of departure he and his baggage should undergo the same cleaning and disinfection.

SOCIETY REPORTS.

LOUISVILLE MEDICO-CHIRURGICAL SOCIETY.

March 23, 1894.

[STENOGRAPHICALLY REPORTED BY C. C. MAPES.]

SYMPATHETIC OPHTHALMIA.

DR. WM. CHEATHAM: This little boy seven years of age, a year ago last November was struck in the right eye by a piece of steel, splitting the cornea, resulting in a cicatrix extending all the way across the cornea, and adhesion of the iris the full length of the wound above and below, with complete closure of the pupil. One year afterward the left eye began to be disturbed. About Christmas there was considerable inflammation in the left eye; this progressed until there was only perception of light, with occlusion of the pupil, with almost total posterior synechia; the iris in some places, where it is not entirely attached you will see the aqueous humor in the posterior chamber pushing it forward. This case brings up several points of interest in which I would like to have the help of the occulists present. One question now, is whether the injured eye is not going to be the better of the two? He now has quick perception of light in both eyes; in passing along the street he can tell when he comes to the gas lights, etc., and can avoid running into objects or persons without any trouble. Ten days ago I took out a small section of the iris of the right eye and also did a small iridectomy on the left. As is usual in these cases, the iridectomy wound was entirely closed in the left eye. This is about the only form of iritis in which we cannot make a satisfactory artificial pupil and for this reason I would advise to wait for months or sometimes years before trying surgery in a sympathetic irido-cyclitis—if you make an iridectomy it will almost invariably close. I believe the time for enucleation of the right eye in the case before us has passed, as by the sympathetic involvment of the left eye the right will likely be of the most service; while it is small and partially shrunken I think it would be of considerable service if we could only get a pupil. Another point in regard to operating on the right eye is whether any lens is present; of course it is uncertain whether the lens is in position. If we could be sure that the lens is intact, then an iridectomy would be the proper procedure; if not an iridotomy would have been the better.

The case brings up another question as to the cause of sympathetic ophthalmia; I do not think professional opinion is at all settled. Whether it travels along the optic nerve, the ciliary nerve, whether it is microbic, or what is the origin of sympathetic ophthalmia. All theories may be correct; one in a given case and another in another. The question comes in here whether it is possible to have sympathetic opthalmia without an opening in the eye-ball. My own opinion is that we can, because we have it in cases in which there is absolutely no history of trauma. I have seen a case where the ciliary body was involved, where the eye was diseased as a result of syphilis, and sympathetic trouble set up in the other eye, where there had been no opening whatever through the sclera. Of course that decides against the theory of the microbic origin of sympathetic ophthalmia, because unless we have a broken surface the microbe cannot enter. In these cases though it is contended that there is a microscopic tear in the surface through which the microbe enters, and thus we have sympathetic ophthalmia.

Knapp divides these cases into "sympathetic irritation" and "sympathetic inflamation," and states that irritation gets well, but the cases of inflammation do not get well. I cannot agree with this statement, as I have seen a great many cases of inflammation get well.

The most remarkable case that I ever saw, was one in which the man could scarcely tell daylight from darkness. I saw the case with Dr. Vance, and under local anæsthesia we enucleated the bad eye and with treatment the patient se-

cured vision of $\frac{20}{30}$ in the remaining eye. I read a report of a case recently where a man had gotten vision of $\frac{20}{20}$. I saw a case with Dr. Dabney some time ago in which the result was vision of $\frac{20}{20}$. These were all undoubted cases of sympathetic inflammation.

There is another point of interest in the case of the little boy before us. Of course we all recognize that enucleation of the injured eye in the beginning would have been the proper thing, still there are some dangers in enucleation; the danger of anæsthesia, some danger of sepsis, hemorrhage, meningitis and death. I have seen two cases of very serious hemorrhage the result of enucleation of the eye. Dr. Cartledge will remember having seen with me two cases of acute insanity following enucleation of the eye. Sometimes erysipelas and panophthalmitis follow as a result of enucleation. Cases of death following enuclation of the eye are not at all common, although we must admit there are some serious dangers connected with the operation. I have seen a series of 500 to 600 cases reported without a single death. Another operator reports 600 cases with only one or two deaths.

I would like for the Fellows to examine the eyes of this little patient and make any suggestions they may be able as to what ought to be done. The case is particularly interesting to me because I have at present six cases of recent trauma with just such injuries as this, in which the question comes up whether enucleation should be done or not. One is in the person of a child eighteen months of age who inflicted an injury to its eyes with a pair of scissors. Another a child brought to be from Indiana, injured her eye while at school with a pencil. As I have said I have under observation now six cases of recent trauma in which the question of enucleation of the eye comes up. I know some of you may say wait for a while and see if any sympathetic trouble sets up; if this is done it may be neglected until it is to late for enucleation. I believe however that this would be wise if the patients could be kept constantly under observation, because we have a period of sympathetic irritation just preceding inflammation. In the case I have mentioned of the child eighteen months old, there is no sight in the affected eye, it is soft and has shrunken fully one-third, the eye being about two-thirds its normal size.

DISCUSSION.

DR. S. G. DABNEY: I agree with what Dr. Cheatham has said, that the time for operative measures in the case presented has passed so far as the eye originally injured is concerned. I certainly favor leaving the injured eye in this case, as I believe the chances of vision are more favorable than in the sympathic eye, in view of the fact that the iridectomy upon it has remained open better than that upon the sympathetically inflamed eye. Outside the case presented by Dr. Cheatham, the subject is extremely interesting and one of great importance. In enucleation for panophthalmitis Noyes after reviewing the whole subject thoroughly, gives the proportion of deaths, one in 4000. Different writers differ widely as regards the advisability of enucleation during acute panophthalmitis. Fuchs in his recent book advises against it. Most American writers as far as I am aware rather favor it. Roosa in his edition of Shmidt-Rimpler's work, states that results from operative measures in acute panophthalmitis are in most instances very satisfactory. The case Dr. Cheatham refers to which he was kind enough to see with me possessed a great many features of interest.

It was the only case of suppuration I have had in operation for cataract. The patient was a lady sixty years of age. Her general health was bad. I had an analysis made of the urine before operating, always feeling somewhat anxious about the case and had some hesitancy about operating, but the examination revealed nothing abnormal. The operation itself seemed to be according to rule as far as that was concerned. The next day she could count fingers easily and there was no pain or other disturbance. Forty-eight hours afterward the suppuration began. Possibly her own imprudence the night after the operation had something to do with it. She passed water perhaps a dozen times during the night, and insisted upon getting up. Panophthalmitis followed and I rather advised enncleation, I did not however, urge operation because many writers on the subject advise that removal of the eye should not be done during an acute panophthalmitis, because of the danger of meningitis and because the dan-

ger of sympathetic ophthalmia following such inflammation is very slight. The patient was unwilling to have the eye removed and asked to have another opinion. Dr. Cheatham and myself consulted in regard to the case, and agreed considering the very slight danger of further trouble, and considering the patient's own wishes, that we would leave the panophthalmitis eye. The case went on without any unusual result for six weeks. She was suffering very little pain, being built up with tonics, etc., in the meantime. Six weeks later she came to my office, saying that three or four days previously she had begun to have pain in her good eye. An examination showed at once that she had an iridocyclitis or iridochoroiditis. In view of the fact that Dr. Cheatham had seen the case previously I asked that he again be called to see her. Of course the only indication was removal of the stump of the panophthalmitis eye, and we advised that this be done immediately. This was late Saturday evening and the patient had then been suffering with sympathetic inflammation for at least four days, but as she did not understand the gravity of the case I was not called earlier. I removed the eye on Sunday morning twelve hours after seeing her; the inflammation subsided immediately and she now has perfect sight in the other eye being 20–20. That was certainly a case of sympathetic inflammation which we have every reason to believe was cured by removal of the offending eye. In regard to operative measures when sympathetic inflammation has already begun or existing and the patient still retain sight—the rule is not to remove the first injured eye, because as Dr. Cheatham has said, often the ultimate vision in this eye is better than the one subject of sympathetic inflammation.

Dr. J. M. Ray: The question of sympathetic ophthalmia and the kind of eye troubles likely to give rise to sympathetic ophthalmia, is an extremely interesting one. We are all agreed that injuries to the eye, especially injuries involving the cornea with adhesions of the iris, or wounds involving the cilary body, are the conditions which are liable to be followed by or give rise to sympathetic ophthalmia. As to whether sympathetic ophthalmia follows any inflammatory disease of the eye without rupture or perforation of the eyeball, is a disputed question. The accepted teaching of the present time in reference to the cause of sympathetic ophthalmia, is that it is microbic in origin. Deutschmann has made some very interesting experiments on this subject, and most authorities agree with him, and if his experiments and statements are true it is impossible to have a sympathetic ophthalmia without rupture of the eyeball.

At the meeting of the American Ophthalmological Society last summer, Dr. Knapp reported a case of sympathetic ophthalmia resulting from a wound of the eyeball with a dislocation of the iris under the conjunctiva without any external wound; after reporting this case in discussing the subject he made the statement that it was the first time he had seen sympathetic ophthalmia follow without an injury of the external coats of the eye. It seemed to be the opinion of those present that sympathetic inflammations were not liable to follow unless there was an injury to the eyeball giving rise to perforation.

Dr. Cheatham will remember seeing a case recently which I have under observation for several years. A young lady came to me three years ago with a small circumscribed spot of chroiditis which has gone on from bad to worse. The inflammation extended form the choroid to the ciliary body producing extensive cyclitis; from that it extended to the iris, but the external tunics were still intact. When I first saw her an examination of the other eye showed one or two small spots on the choroid with one considerable side spot extending far out just back of the lens. She began to have some little sensations referable to the outer eye. Things looked steamy at times. She went on this way for probably six months with the sight of the other eye remaining as good as formerly. Meantime she went to Chicago and consulted her brother (an oculist), who saw the case at about the time when the inflammation was worst in the first eye; he sent her back here and asked me to take charge of the case and institute any treatment I thought necessary. I did not look upon the case very favorably and thought she would probably lose the eye. A month or six weeks afterward the patient decided to have the eye removed. I took the eye out. The other eye is just about the same as before.

If the teaching with reference to the cause of sympathetic ophthalmia is correct, it would seem that it is impossible for this this condition to occur unless there is a rupture of the eyeball.

In regard to enucleation during panophthalmitis: I have done this in two cases, and the patients seemed to do just as well as they would under other circumstances. I know objections have been raised to the procedure, but I would not hesitate to enucleate the eye during panophthalmitis, if the indications of the case demanded it.

DR. WM. CHEATHAM: Referring to the case which Dr. Ray states I saw with him where the patient had cyclitis and iridochoroiditis: Books state that the thing which produces sympathetic ophthalmia is disease of the ciliary body. That patient certainly has a diseased conditlon of the ciliary body.

To show that Dr. Ray is mistaken in his remarks in reference to Dr. Knapp's paper and discussiou of the same, I will read the following extracts from that paper and discussion, from the transactions of the Society before which the paper was read.

Dr. Knapp says: "That this accident, twenty-five days after the injury, led to the development of typical sympathetic ophthalmia, is not unprecedented if the cases of subconjunctival dislocation of the lens are included in this class of injuries."

"DR. O. F. WADSWORTH, Boston: I should like to speak of a case which was a very melancholy one and which occurred some ten or twelve years ago. In this case a spit-ball blown from a toy gun ruptured the sclera in the ciliary region without rupture of the conjunctiva so far as I could make out. The boy was twelve years of age and an only son.

"He came the next day after looking out of the window at the bright sun. There were numerous dots on the membrane of Descemet, the pupil was sluggish and atropine showed posterior synechiæ. The other eye was enucleated the same afternoon, but he lost sight in the remaining eye within a couple of days. There had apparently been no wound in the conjunctiva and no tenderness on pressure."

"DR. J. F. NOYES, Providence, R. I.: wish to relate the history of another case in which I was in doubt what to do. A young man playing base-ball was hit by the ball on the cheek bone and stunned, but I did not see the case until three weeks afterwards. He then came on account of failure of vision in the eye on the injured side. I also found symptoms of sympathetic trouble in the other eye. I advised enucleation of the first eye, but to this he did not consent. He became totally blind, but neither eye showed any great amount of inflammation. The question arises whether or not the second eye would have been saved if the first had been removed?"

"DR. HERMAN KNAPP, New York:—With regard to this case, there was an unbroken conjunctiva. There are in the whole realm of literature only a few of these cases where sympathetic trouble followed where there was an unbroken conjunctiva.

"Sympathetic ophthalmia following a non-penetrating wound is so rare that Boé gives the rule that under no condition need an eye be removed where there is no external injury. That was the case here. I do not think that any one of you have seen sympathetic ophthalmia without an external lesion of the eyeball. It is a process of bacterial origin. Nevertheless there are six cases, and this is perhaps the the seventh, where there was no external injury."

"DR. SAMUEL THEOBALD, Baltimore.—Dr. Knapp has stated that there are only six cases recorded of sympathetic ophthalmia following injury to the eye without external wound. This, perhaps, may be true, but I think that there have been many cases reported of sympathetic ophthalmia where there has been no wound at all, where there has been inflammation of the ciliary body or deeper structures of the exciting eye without traumatism."

"DR. J. F. NOYES, Providence, R. I.—Will Dr. Knapp explain the case that I have just reported where the blow was received on the cheek without injury to the eye, and there was little or no appearance of inflammation in the eye, yet sympathetic trouble followed?"

I have certainly seen cases where there was no injury to the eye and yet sympathetic ophthalmia developed. I still believe that it is possible for this condition to occur without an opening in the eyeball.

DR. S. G. DABNEY: Homor, of Zurich, whose clinical experience in this direction was probably as great as that of any-

body in the world made the statement that sympathetic ophthalmia possibly may occur without an opening in the eyeball, but these cases or instances are very rare. He is in full accord with the theory that these cases are microbic in origin, but states that they may occasionally occur without an opening in the eyeball which can be detected.

ABDOMINAL TUMOR.

DR. A. M. CARTLEDGE: This patient is Mr. H., aged forty years. He has an abdominal growth or displaced viscera, but which I am not yet able to say. The enlargement was first noticed when he was eleven years of age, while being treated during an attack of typhoid fever. Prior to this he received a severe kick about the center of the abdomen (when seven years old) by a mule. When twenty-two years old he suffered with an attack of what was termed congestion of the liver and stomach. He was in bed between three and four months, and was an invalid for a year subsequent to that time; had hemorrhage from both the stomach and bowels on that occasion. After that he occasionally, especially during the summer, suffered from severe bilious attacks, so-called. When thirty-two years old he had the second one of these attacks of congestion of the liver and stomach. Three years ago he had an attack of decided jaundice. Since he was eleven years old he says that he has never been able, on his farm in Virginia, to do any work requiring him to bend over, on account of the soreness which has always been present and the inconvenience caused by assuming a stooping position, and at times he would have this uncomfortable soreness when not attempting to stoop.

The latter part of July I was called to see Mr. H., suffering from intense abdominal pain which was very vague as to its seat. There was some little constipation but the attack had come on with great nausea and vomiting. In examining the abdomen I discovered this enlargement and called his attention to it. There was considerable swelling of the abdomen, tympanites and pain, requiring the administration of morphine for its relief, lasting for about twelve hours. There was some jaundice during this attack, but no especial tenderness referable to the region of the liver. The greatest point of tenderness was immediately over this enlargement. After resting a few days in bed, he was able to get up and walk about, but in August had a recurrence of the pain. He recovered from this attack very slowly; the jaundice, however, quickly cleared up and after two months sojourn at several watering places, he finally got back to his normal condition. Since that time his health has been fair; he has not lost much in flesh, but still has this tenderness on bending, and the question in the case is simply one of diagnosis as to the nature of the trouble. There is one point which may be of some diagnostic value, and of some assistance. For a number of years he remembers distinctly that this enlargement was possessed of great mobility which has been gradually diminishing until the present time it is more or less fixed in its situation.

DISCUSSION.

DR. J. A. LARRABEE: From the examination I made of this case, I believe it is a detached or wandering spleen caused by the kick of the mule.

DR. J. W. IRWIN: I find that there is no dullness on percussion in the region of spleen, or where the spleen ought to be, but there is dullness on percussion over the left kidney and over the region of the liver. I believe it is a displaced spleen and that it is attached to the mesentery. The hemorrhages that he has had and other troubles may be readily explained by the enlargement of this organ and its dislocation.

DR. J. B. MARVIN: The tumor is certainly behind the gut; it is not the shape of a kidney, and I am inclined to the opinion that it is the spleen.

Dr. J. M. Ray presented a paper on

ADENOID GROWTHS IN THE DOME OF THE NASO-PHARYNGEAL SPACE.

(See page 74)

DISCUSSION.

DR. WM. CHEATHAM: The paper is such a thorough review of the subject up to date that there is very little left to be said. I would also like to add to the paper that diseases of the ear are the most serious complications or dangers from adenoid

growths. Another serious feature is obstructed respiration. The nose is not only intended for olfactory purposes, but also for filtering the air and rendering it more moist. It is said that even the coldest atmosphere passing through the nose, by the time it reaches the larynx is heated to nearly the body temperature. Unless the air is filtered and heated, and unless it is rendered properly moist when it enters the lungs, it is impossible for the proper interchange of gases to take place, as between oxygen and carbonic acid gas. So the question of removal of adenoid growths is not only important from the fact that they are frequently the direct cause of ear troubles, but it is also important in order to secure nasal respiration. Air entering the lung through the mouth, cold, not moistened, not filtered makes it impossible for the proper interchange of gases to go on.

I differ with Dr. Ray in regard to anæsthesia: I do not think I have ever given general anæsthesia to remove growths of this character. I put a gag or cork in the mouth, get some one to hold the patient, then under local anæsthesia removal of the growths can be easily and quickly accomplished. I am afraid of general anæsthesia in these cases since I saw a death in the London Hospital resulting from cocaine, where a child was to be operated upon for adenoid growths.

DR. S. G. DABNEY: Referring to Dr. Cheathem's remarks: I differ with him in regard to the anæsthesia—in young children we ought to give chloroform. I recently operated upon a child who had been operated on in another city for adenoid growths without anæsthesia, and I found quite a large mass remaining which was thoroughly removed with the curette under anæsthesia.

As regards age: I have operated upon children two and three years old, and a number from fifteen to twenty years old. In older children or half grown people, I am in the habit of drawing the palate forward by means of the palate retractor, then passing a curved probe around it and applying cocaine with a pledget of cotton (not the spray) removal may sometimes be accomplished without general anæsthesia.

I believe it to be a fact that many cases such as Dr. Ray describes are overlooked; they may present symptoms not quite so marked as he mentions; there may be no ear symptoms and not much mouth breathing. I recall one just now; a child was brought to me with a symptom which has not yet been mentioned—vomiting in the morning before, and sometimes during breakfast. He also had obstructed breathing. An examination with the finger showed that there was a mass of adenoids in the roof of the mouth. They were scraped away, and as a result the vomiting, obstructed breathing and all symptoms were relieved. The vomiting was probably caused by the mucus and discharges which had accumulated about the adenoids over night and was loosened by the warm food at breakfast.

Suppuration of the middle ear may often be the result of adenoid tissue in the roof of the mouth. I recently operated upon two such cases in the same family. It is my custom to always make a thorough examination and search for adenoids in every case of suppuration of the middle ear, and in operating for these growths I invariably give chloroform, in small children.

DR. J. A. LARRABEE: From the standpoint of the general practitioner: The statement made by the essayist that a spontaneous cure may be looked for by arrival at adult years, would at first sight seem to lessen the importance of attending to it in childhood. That importance is increased, however, when we consider the consequences that may accrue from such conditions. I am satisfied that in my earlier practice I did not fully appreciate the condition under discussion, and saw many cases of incomplete development of the chest, and the prow or pigeon breast, and some with curvatures and deformities of the shoulders due to this adenoid condition, which I did not then recognize. When we come to consider the consequences of improper breathing in children from three to fourteen years of age just spoken of by the essayist, we find that while the disease admits of spontaneous cure with growth and development, the consequences produced are not relieved.

I was somewhat surprised to learn that in the Johns-Hopkins Hospital recently some thirty cases were found in the ordinary run of clinics operated upon for adenoids, the usual method being without instruments; the patients being

young and the growths soft, they were removed with the finger nail. I am satisfied that the percentage spoken of by the essayist is in moderation. I believe these cases are more frequent than are recognized. One of the most noticeable symptoms of adenoid growths is the facial expression; if there is anything that can be diagnosed by physiogomy, it is the condition under discussion.

Dr. J. B. Marvin: I think the general practitioner in the city who does not look in the throat nowadays, as well as examining the mouths of all male children has no excuse, as he has certainly heard enough about such conditions. There is one point I think Dr. Ray did not make strong enough. It seems to me that we can make a second division very clearly in these cases, and in the worst class there is not only adenoid growths, but an arched palate, a narrow jawbone encroaching upon the fauces. That seems to me to be a more serious form and more likely to be associated with pigeon or chicken breast than the other.

There is another point in regard to the etiology: Six months ago a child was brought to me for another trouble; a handsome little fellow, and I noticed that he had the habit of jerking his head back. Upon interrogating the mother, she said he was born that way, that he had a "death mark." She having seen a woman die while pregnant. Upon examination the trouble was found to be well-developed adenoid growths, the removal of which corrected the habit.

Dr. W. O. Roberts: I have had two cases of the nature under discussion, both of which were operated upon by Dr. Ray. The point brought up by Dr. Marvin, the narrow jawbone with arched palate, was very marked in one case, less so in the other. Both patients had trouble in the hearing, and in one of them the hearing was very markedly interferred with; not only was the child subject to frequent attacks of otorrhœa, but it was accompanied with severe pain. Since the operation was performed there has been no trouble in any respect in either case. In both cases there was a very marked improvement in the general health. In the case where there was a purulent discharge, the mother could always tell when it was coming on, by the fact that the ear would become very red; the next day it would have intense earache, then directly afterward discharge from the ear would be noticed. Chloroform was given in both cases, and I was struck with the ease with which the operation was performed.

Dr. J. L. Howard: The question that Dr. Roberts has brought up concerning the giving of chloroform in cases of this kind is of great interest to me. I have administered chloroform in six cases for removal of adenoid growths, rather two cases in which there were polypi of the nose and a great deal of hypertrophy in this region, and four cases of adenoid growths, and I have always had trouble in giving the anæsthesia; I came very near having three deaths. I have probably given chloroform three hundred times for different operations, and have experienced no trouble except in the six just mentioned. It may be on account of the obstruction in this region, and I have never administered the anæsthetic for this condition without a great deal of fear.

Dr. H. A. Cottell: About a month ago Dr. Ray and myself went out to operate upon a little boy three years old who had adenoid growths, and who had all the symptoms the essayist has so graphically described. I was particularly struck with the wonderful facility with which the operation was done. The patient was put profoundly under the influence of chloroform, and the adenoid vegetations were scraped out with such speed and facility as to excite my admiration. The operation was practically completed in a few seconds. Hemorrhage was free for a time, but soon subsided. I have seen the patient several times since and I find the result perfect. It seems to me that an operation for the removal of such growths should not be undertaken without an anæsthetic.

Dr. J. M. Ray: When I first commenced operating for adenoid growths I probably did about half my operations without an anæsthetic. Where we have a child from nine to ten years old, rather tractable the operation may be done without an anæsthetic by means of the curette.

The specimen which I show you of adenoid growth was removed from a child eleven years old. The trouble dates back to an attack of diphtheria. When the child was five years old he suffered quite a severe attack of nasal diphtheria, and it was thought there was paralysis of the soft palate, It was treated by spraying,

washes, etc., with little or no benefit. The most marked symptom was mouth breathing. I sprayed the throat with cocaine, and with the heart shaped curette which I show you at the second attempt brought the adenoid growth away. In young children two or three years old, I think it is always best to give an anæsthetic, as the operation of necessity is somewhat painful. The rush of blood is usually quite free at first but soon subsides, and I have had no after effect whatever from the operation. I have very often removed these growths without the aid of any instrument, simply using my finger nail.

CONTINUED DISCUSSION OF APPENDICITIS.

DR. A. M. CARTLEDGE: At a meeting of this society four weeks ago, I exhibited three appendices illustrating three stages of the pathology of appendicitis. The first was the result of an operation that day, the appendix showing a stenosis commencing about half an inch from the base, with the extremity very much enlarged and distended with liquid feces. I split open the appendix in order to demonstrate the point of narrowing which I thought was of considerable interest. Second a necrosed stump where the appendix had almost entirely disappeared, and third a large perforated appendix. It seems that the appendix which was slit open excited the most discussion, the others having apparently been overlooked.

In view of the various opinions held by members of the society, I think the suggestion made by Dr. Vance that we exhibit before this meeting such appendices as we may have preserved in order to illustrate the pathological conditions, an excellent one. I have accordingly brought twelve specimens for examination, which were all I could get hold of to-day. There were two or three other appendices that I wished particularly to present, but they could not be located in my hasty search among other specimens. One very pretty specimen showing volvulus of the appendix with rupture, was lost in removal.

I have very little to add to what I have already said on the subject; the specimens themselves illustrate the different pathological conditions, and by an examination I believe you will all agree that all of them bear evidences of pathological conditions demanding operation. Perforation had occurred in nearly every case as will be seen by the specimens, abscesses had formed in most of them and pus was present in all except one; that was the case reported four weeks ago where there was stenosis and distal distension. Many of the patients had been subject to recurrent attacks of undoubted appendicitis, a few were operated upon *in extremis*, others a few hours after the first symptoms developed. One case was treated several weeks for typhoid fever before diagnosis of appendicitis was made. In only one case, I believe, have I found fecal concretions, and have never encountered a foreign body in the appendix.

DR. TURNER ANDERSON: What has been your percentage of recoveries?

DR. A. M. CARTLEDGE: I have had twenty-two cases of appendicitis up to the present time, with four deaths. This number includes cases of general septic peritonitis the result of appendiceal disease.

DR. T. L. MCDERMOTT: Of the twelve cases represented by the specimens before us, how many died?

DR. A. M. CARTLEDGE: Three died out of the twelve.

DR. A. M. VANCE: I have here eighteen appendices, part of which were removed by myself, the balance by Dr. W. C. Dugan. I will not take time to refer to the cases in detail with the exception of one or two. The specimens all bear evidence of a pathological condition demanding operation, and this I think will be apparent by even a casual examination.

At the last meeting of this Society the case of Mr. T. was mentioned by Drs. Anderson and McDermott: I would ask the privilege of reading the report of that case which was made to this Society the day after the operation, and the discussion, showing that pus was present and the perforation in the appendix was seen by all those who witnessed the operation or subsequently examined the specimen.

"FROM REPORT MEDICO-CHIRURGICAL SOCIETY, MARCH 17TH, 1893. CASE OF APPENDICITIS—OPERATION—DEATH.

DR. A. M. VANCE: I was called by Dr. McDermott yesterday at three o'clock to see a gentleman; German, forty-nine years of age; very fleshy. He gave the history that in January he had some bowel trouble

which yielded to castor oil and he recovered. In February he had another attack preceeded by diarrhoea which was relieved. For a week prior to the time Dr. McDermott was consulted (he was called sixteen hours before he asked me to see the case) the man had been feeling a little "out of sorts" but he thought it was an attack similar to those he had formerly suffered with and kept around attending to his business. At five o'clock Wednesday afternoon he was taken suddenly with great pain in the abdomen, and he got up-stairs with difficulty and went to bed. Dr. Geo. F. Simpson was called in and gave the man a hypodermic of morphine. Dr. McDermott came several hours later and found the man with marked symptoms of shock; he made diagnosis then of probable appendicitis. It was necessary to administer more morphine on account of the severe nature of the pain, salines were given without result, pulse gradually increasing in frequency, temperature 103° F. at one time. I saw the patient at three o'clock yesterday; found temperature 101½° F. pulse 120; abdomen very much distended over the whole area of the peritoneum, tenderness being particularly referred, however, to the McBurney spot. We advised an operation at once.

Drs. Roberts, Kelly, and Anderson afterward saw the case. Last night at seven o'clock the abdomen was opened; an incision was made between the anterior superior spinous process of the ilium and the umbilicus, the man was very fat, fully three inches of adipose tissue being encountered before the true wall was reached. As soon as the peritoneum was punctured pus came out in considerable quantities. With some little difficulty the appendix was found and removed. At the time of the operation the man's pulse was 128. The appendix was quite small and as it was lifted out the distal end was torn and separated, but before it was torn Dr. Roberts and I detected a perforation about the size of a match in the lower portion. The two pieces of appendix have been carefully put together by Dr. Anderson and you can plainly see signs of great localized congestion and make out the perforation. The appendix between this congested end and the cæcum was very small and white. The man had general suppurative peritonitis, rupture having taken place probably at five o'clock day before yesterday afternoon when the severe symptoms developed.

This instance shows how treacherous these cases are and how important it is to make early diagnosis if possible, so that relief may be obtained by sergical procedure. I have operated twice recently where perforation of the appendix was about to take place and the patient recovered; I have operated twice where perforation had already taken place and both patients died. This man died four hours ofter operation in shock. He secreted very little urine for several hours prior to operation, and two hours after the operation had been performed I catheterized the bladder and drew off about an ounce of urine; I examined it and found albumen.

DISCUSSION

DR. T. L. MCDERMOTT: Dr. Vance mentions two cases of appendicitis in which he operated before perforation took place and in which the operation was successful; also two cases in which perforation had taken place which were not successful. This is the point I want to call attention to. I have had in the past week two or three cases of colic in which there was evidence of as much distress as this patient had. I have frequently had cases of colic in which there were symptoms apparently just as severe as have been found in cases where appendicitis has been made out, and where peritonitis has followed, and it has been a serious question in my mind whether often in cases where appendicitis has been diagnosticated, they were not purely cases of colic. While this man had the general symptoms of appendicitis, still owing to his having had several similar attacks and owing to the peculiar condition of the patient, I did not feel that I was justified in saying so positively and advising operation. I do not believe if Dr. Vance had been present when I first saw the patient, he could have said positively that it was appendicitis. The question is whether it is wise to recommend an operation as serious as a laparotomy in cases that may prove to be nothing more than ordinary colic. I am sorry, now, however, owing to the final outcome of the case, that Dr. Vance did not see the patient with me earlier in the attack; still as I had treated this patient in several

similar attacks, I had no reason to believe that relief would not follow ordinary treatment as has been the case on previous occasions. How can we discriminate in these cases between ordinary colic and appendicitis when the symptoms are often identical? The responsibility is very great and certainly it would be a mistake to go into the abdomen in ordinary colic. It is a serious question in my mind whether laparotomy is indicated in these cases. I do say frankly however, that in the two cases upon which Dr. Vance operated I believe the result would have been the same with or without operation. While I am a little chaotic in regard to these cases I believe in another case I shall summon consultation earlier, but in the case reported I do not think operation would have been successful had it been performed earlier. The operation was performed twenty hours after the seizure, four of which were necessarily lost in the attending consultations and subsequent preparations.

DR. TURNER ANDERSON: In the case reported I do not see how it would have been possible to have made a diagnosis that would have justified a laparotomy earlier than was done, especially as the patient was able to be up and attend to his business only a few days prior to his death, and further as he had been subject to frequent attacks of abdominal trouble which yielded promptly to ordinary treatment.

DR. A. M. VANCE: I do not believe it is ever possible to tell just exactly the condition we will encounter when the is opened, but I do think diagnosis can be made with sufficent accuracy to justify operation in nearly every case. Drs. Anderson and McDermott in my opinion, have both laid too much stress upon the dangers of a lapartomy. It is now a well established fact that laparotomy in competent hands and under favorable surroundings is a comparatively safe surgical procedure, and the operation performed last night had it not been for the patient's serious condition, could have done no possible harm. Therefore, I think in the not far distant future all of these cases will be operated upon in the stage that Dr. McDermott first saw this patient. I believe these cases ought to have the benefit of the doubt, and a laparotomy be done for the purpose of diagnosis; I believe that this will eventually be the practice.

In regard to the differential diagnosis I would not be so presumptious as to say positively in every case that I could tell exactly the conditions that would be encountered when the abdomen was opened, but I cannot think of anything else but perforative appendicitis or perforation of the bowel owing to some other cause that would produce general peritonitis so quickly in the male except traumatism. Of course the perforation of typhoid fever, is not considered in this case, as there is no such history. Dr. McDermott made the diagnosis of appendicitis when he first saw the patient and I firmly believe if operation had been performed then, the chances would have very favorable for recovery.

(DR. VANCE CONTINUED.)

In the discussion two weeks ago, the question was asked as to how many cases of appendictis had probably been treated by the different medical men in which the diagnosis was never perfected, the patients died and the deaths ascribed to *peritonitis*. Dr. A. M. Cartledge and myself in the last few days have looked over the Health Officer's statistics and death reports and we have found recorded in the last twenty-three years 168 deaths in males from acute peritonitis, the average age being twenty-eight years. Almost every prominent physician of Louisville has his name affixed to some of these death certificates. We surgeons claim we have the right to believe that the vast majority of these cases of acute peritonitis—so-called idiopathic peritonitis—in the young male and a great proportion in females, are due to appendicitis, and I think this is a great argument in favor of surgical procedure in these cases. The physician does not know, or cannot be absolutely certain, that he has a case of appendicitis until he sees the specimen and the surgeon does not know positively.

Certainly the specimens before us are diseased appendices and they would have caused death in every case had not operation been performed.

DR. A. M. CARTLEDGE: In making the investigation spoken of by Dr. Vance, we excluded all cases of tubercular peritonitis; all cases of peritonitis in the female and all cases where the peritonitis was said to have been the result of injury, and found

as has already been stated 168 cases of acute peritonitis occurring in the male in the city of Louisville within the last twenty-three years, and the death certificate was so endorsed. From past experience it is our belief that a large majority of these cases were appendicitis.

DR. T. L. MCDERMOTT: Referring to the quotation Dr. Vance has read from a previous meeting of this society—perhaps it might be well to add a few words in explanation. I had attended the patient, Mr. T., in two previous attacks in which exactly the same symptoms had developed, if anything he was more seriously ill than in this instance, and he had recovered under the ordinary anodyne treatment, opium, salines, etc. I will state also that Dr. Simpson had been called in the last instance previous to my seeing the patient, and had given a hypodermic of morphine, which masked the symptoms to some extent, but at that time I had supposed the trouble was an ordinary attack of colic. I visited him again the next morning and as the temperature was elevated, and he was so profoundly impressed, it then indicated to me that the trouble was more serious in character. Dr. Vance was then called in consultation and the operation was performed shortly afterward. I feel that this patient had the benefit of an operation as early as any physician could have reasonably made a satisfactory diagnosis. While the shock was beyond what we would expect in ordinary colic, still I have seen patients much more profoundly impressed in renal colic and with similar symptoms who recovered without operation. The whole difficulty in these cases lies in the fact, as I stated in a paper read at the last meeting of this society, of our being unable to make a satisfactory diagnosis. I have no doubt if the diagnosis were made at once, if perforation had occurred with healthy structures surrounding it, if the surgeon were called to the case immediately and operate, it would be the proper and only thing to do; but who is able to make such a diagnosis? In the case under discussion I believe the patient would have died in any event; and I further believe that if Dr. Vance had seen the patient earlier a satisfactory diagnosis could not have been arrived at sooner. While I was inclined to the opinion that it was a case of appendicitis, still there was an element of uncertainty about it, and I felt justified in waiting. Again I had seen this patient get well in several previous attacks in which his suffering was seemingly equally intense, and had also seen numerous other cases having about the same line of symptoms which recovered without operation under the ordinary treatment. How can we discriminate in these cases?

I think the matter is still subjudice, and in writing my paper read before the last meeting of this Society, I did so purely in the spirit of research hoping that it might result in our getting at the bottom of the whole matter and formulating something definite in the way of indications for operation, etc. The only solution of the problem in my estimation is to enter into just such discussion as we have been doing, to tabulate each case in which operation has and has not been done, and the result will be a better understanding of the situation. Possibly in that way we may be able to illuminate the field that is now certainly in darkness in the medical mind.

The Medical Raven.

Once upon a midnight dreary,
The doctor slumbered weak and weary
And all the town could
Hear him snore.
While he lay there sweetly napping.
Suddenly there came a tapping
Like a ramgoat madly rapping
His hard head
Upon the door.
"Get thee up," a voice said loudly,
"Come in haste," it added proudly,
Like a man who owned a million
Or much more.
But the doctor never heeded:
Back to dreamland fast he speeded,
For such men as that he needed
In his practice
Nevermore.
For long months that man had owed him,
Not a cent he'd ever paid him,
And the doctor now will dose him
Nevermore.

BOOK REVIEWS.

Clinical Diagnosis. By Albert Abrams, M. D., (Heidelberg), Professor of Pathology, Cooper Medical College, San Francisco, Cal.; Pathologist to the City and County Hospital, San Francisco; Author of "A Synopsis of Morbid Renal Secretions," etc.; President of the San Francisco Medico-Chirurgical Society, (1893–1894); President of the Alumni Association of Cooper Medical College (1888–1889). Third edition, revised and enlarged. illustrated. New York. C. B. Treat, 5 Cooper Union, 1894. Price, $2.75.

The fact of a third edition of this manual being issued shows its popularity. It has been revised and enlarged and now comprises 273 pages (including a 19-page index) with 28 illustrations. The physical signs associated with disease of the organs in the various cavities of the body are given in minute detail and include many recent additions to the methods of examining these organs. In palpation of the kidney, the author recommends the recumbent posture. In malpositions of this organ it is no doubt better to remain in the erect posture with the abdominal wall relaxed by bearing the weight of the body on arms.

There is a brief account of bacteria with methods of staining.

An appendix contains a chapter on insanity, and many synoptic tables. The work, brief though it be, covers the field pretty thoroughly and the general practitioner will find it very useful in refreshing his memory on many old points, and adding perhaps not a few new ones to his means of diagnosis.

W. E. P.

A Manual of Therapeutics. By A. A. Stevens, A. M., M. D., Lecturer on Terminology and Instructor in Physical Diagnosis in the University of Pennsylvania; Demonstrator of Pathology in the Woman's Medical College, Philadelphia; Physician to St. Mary's Hospital and to the South Eastern Dispensary; Pathologist to St. Agnes Hospital. Philadelphia, W. B. Saunders, 925 Walnut Street, 1894. Price, $2.25.

"This Manual has been prepared," says the author, "especially for students with the hope that it may serve as an outline of modern therapeutics, to be filled in and extended by systematic study of the larger works."

The drugs havebeen arranged in alphabetical order according to Latin names.

A chapter on "Incomptability in Prescriptions" has been added by Joseph W. England, Ph. G. The book consisting of 435 pages, includes chapters on "Physiological Action of Drugs," "Drugs," "Remedial Measures Other than Drugs," "Applied Therapeutics," "Incompatibility in Prescriptions," "Table of Doses," and is well indexed both as to drugs and diseases.

The large supply of manuals is some index of the demand for them. This one will be useful not only to the student, but the busy practitioner may often refer to it with profit.

W. E. P.

Differential Diagnosis of Common Diseases of the Eyes. Designed for the use of general physicians by W. F. Conners, M. D., Oil City, Pa. Price, 50 cents.

The author notes that this chart is only intended for general indications, to give the family physician a comparative table of the common diseases of the eye. The intention is to help the family doctor to make a diagnosis without instruments of special knowledge.

W. E. P.

Sexual Neurasthenia (Nervous Exhaustion). Its Hygiene, Causes, Symptoms and Treatment, with a chapter on Diet for the Nervous. Third Edition, with Formulas by Geo. M. Beard, A. M., M. D., etc. Posthumous Manuscript, edited by A. D. Rockwell, A. M., M. D., etc. Published by E. B. Treat, 5 Cooper Union, New York, 1893. (Price, 2.75).

The late learned Beard says as to neurasthenia:

"There are two points in the male and female that suffer especially when laboring under nervous exhaustion or neurasthenia, *i. e*, fifteen lines under the prostate gland in the males and thirty lines across the ovary in the female."

These are the prologue of the coming nations; these represent the history of past nations—no medical philosopher except Bilroth ever announced such living gems. Hunter is gone, Beard is gone, and Bilroth is gone. They are gone to the land where an Emperor governs the empire of litters. Nothing shows the man so much as the stamp of individual ideas in every page of his book. It is equal to a liberal education to be allowed to lecture continuously, as did he, in such a school as the University of New York. This book, the third edition, contains 282 pages of strong medical knowledge. The researches began prior to 1868.

Until lately general neurasthenia has been confounded with hysteria, simple hypochondria, some form of insanity, and with the various diseases of the nervous system.

The definition of neurasthenia is not so simple as some would suppose, nor is its causation simple but complex, as is its treatment more medical than surgical, and at times both together, not to direct our attention to one single fault as to emissions solely, to insomnia alone, or to the urinary deposits, but to dig at the root of the diseased tree rather than to lop off each and every effected branch.

Most of the recent works on neurasthenia have been in the German language and they all give especial attention to the digestive and not to the sexual form of the disease. Of the twenty-nine writers in the list only two are in English.

W. F. Mittendoff was of great service in making the urinary analysis. The inferences therefrom are that:

1st. A close attention to the study of the urine showed that spermato is a frequent attendant on all kinds of neurasthenia in the male and indeed in many other debilitating diseases.

2d. That oxalates, phosphates and urates occur in most of these conditions.

3d. That the urine in very nervous persons varies every hour in the day, responding much to the general systemic condition, and especially to the defects of digestion.

4th. That the custom of naming diseases from the character of the urine is fallacious and deceiving.

The author's original essay on neurasthenia was three times declined by medical journals for publication, yet finally become the corner stone of the temple for the treatment of that condition. It was finally published in the *Boston Medical Journal* in April 29th, 1879. The Germans accepted it at once. The original of the work on "American Nervousness" was in effect the chapter on the "Causes of American Neurasthenia," and it was not thought by the publishers to be of any special bearing and scarcely worthy of appearing in print—and indeed it was thought that few would read it, but its repeated endorsement by Mr. Herbert Spencer, in 1882, aroused some interest on the subject.

J. J. C.

Maladies Infectieuses Parasitaires des os, Par Michel Gangolphe, Professeur agrege a la faculte de medecine, chirurgien en chef designe de l'hotel-dieu de Lyon. 714 pp. G. Masson, publisher, Paris, 1894.

This work on the infectious and parasitic diseases of bones may be said, to use a thread bare phrase, to fill an actual want or gap in the medical literature for, although in recent years a large number of articles and monographs have been scattered through the literature on the various forms of infectious and parasitic affections of the bones, there has not appeared a full and comprehensive work on these affections. The lesions and characteristic symptoms are continually being studied with the result that they are approaching clearer and better understood types. Under the name infectious and parasitic diseases of the bones he presents those affections of the skeleton generally thought to be dependent upon the action of pathogenic agents, more or less highly organized; microbes or parasites. Tuberculosis, the different varieties of infectious osteo-myelitis, lepra, hydatid cysts, and actinomycosis are undisputed types. The syphilitic affections, though the exact nature of the pathogenic agent is not yet understood, he has not hesitated to include as well in this classification. The osseous and articular deformations observed during the course of chronic suppurative pleuro-pneumonic processes also are described. The first chapter of the work is wholly devoted to a recapitulation of the generally prevading ideas on the anatomy, physiology and pathology which are indispensible to an exact knowledge of these pathological processes. The following sections treat successively of tuberculosis, of the different varieties of infectious osteo-myelitis, the osseous and articular deformities noticed in connection with chronic suppurative states of the lungs and pleura, lepra, the syphilitic alterations in the skeletal system, hydatid cysts and actinomycosis. The bibliographic indications of French and foreign works are quite complete. The influence of Ollier, his teacher, is more or less observed throughout the work, especially in the treatment of the different conditions. Indeed, it was in his service that the foundations of the work were laid. The writer deserves thanks for collecting the scattered literature on this subject, and presenting it, with his own observations and deductions, in such a clear and concise form.

F. H. P.

Early Diagnosis of Gastric Carcinoma.

In the *Deut. med. Woch.*, Cohnheim of Boas's Poliklinik contends that it is possible to make a fairly certain diagnosis in the absence of a tumour. The old idea that chronic gastritis is accompanied by lactic and fatty acid formation is disputed, but in cases of carcinoma an intense reaction to Uffelmann's test for lactic acid appears. For such an intense reaction stagnation of the gastric contents and a lasting absence of free hydrochloric acid are necessary. If only one of these conditions is present, as in chronic gastritis or dilatation of the stomach, such a reaction does not appear. The author relates a case in which a simple ulcer was suspected, and in which treatment had no lasting effect. When the stomach contents were at length examined no free hydrochloric acid was present, and Uffelmann's test gave a marked result. The stagnation of the gastric contents here was against chronic gastritis, where the food passes into the intestine within the usual time. Later, besides other symptoms, there was marked wasting, and yet no tumour could be felt. At the necropsy a limited growth was found at the pylorus. The author points out that in this case, in the absence of recognizable tumour, a correct diagnosis was made six months before death, chiefly from the constant and marked presence of lactic acid. Within eleven months ten such cases were seen without recognizable tumour, all of which gave a positive reaction with Uffelman's test, and yet no such reaction was ever observed in cases of gastrectasis or of chronic gastritis with absence of free hydrochloric acid. The author lays stress on the importance of early diagnosis in regard to the question of possible removal. Lastly he refers to the new test proposed by Boas for lactic acid in the stomach contents (Epitome, November 4th, 1894, par. 364.)

Ozæna.

Dr. Stein obtains in ozæna most remarkable results from painting the nasal fossæ with a solution of trichloracetic acid. The painting is done by means of a piece of cotton-wool steeped in a solution (one-tenth per cent.) and fixed on the point of a flexible wire. The operation is done three times daily for the first few days and then once a day. The strength of the solution is gradually increased.

CURRENT LITERATURE REVIEWED.

IN CHARGE OF ELLISTON J. MORRIS, M. D., AND SAMUEL M. WILSON, M. D.

IN THE TEXAS SANITARIAN

for June, Dr. J. H. Sears, in his annual address as President of the Texas State Medical Association, spoke of the *History of Medicine in Texas*, giving a very vivid description of the life of a physician in Texas half a century ago, and the changes which have taken place.

He then spoke of the increasing number of dishonest and untrustworthy men practicing medicine and surgery in the state, and appealed to his hearers to assist in the passage of a law restricting and discouraging this.

Hon. Clark Bell has an article on

Railway Spine

which he read before the National Association of Railway Surgeons.

The term, he says, when used, as its inventor intended, to mean a vague pathological condition of the spinal cord, usually not accompanied by external injury to the spine, but due to some incident of railway travel is inexcusable.

Quoting the definition of Erichsen he states that it has no definite meaning, may cover any subjective symptom at all, and stigmatizes it as an invention intended to help malingerers to bleed corporations, and used for no other purpose.

Other papers in this issue are on "Prevention of Consumption," by Dr. R. M. Swearingen, and "Dress as a Factor in Diseases of Women," by Dr. E. C. Collins.

IN THE BRITISH JOURNAL OF DERMOTOLOGY

for June is an article by Dr. Wallace Beatty on

Seborrhœa.

The article begins by quoting Unna's statement that the term seborrhœa is commonly applied to two totally different diseases; that "seborrhœa oleosa" is a hypersecretion of the sweat glands, and that there is no dry seborrhœa, or deposit on the skin, of firm products of sebaceous glands.

These dry seborrhœas he says are chronic inflammations of the skin.

His clinical description states that seborrhœic eczema usually starts at the scalp and there is a history of dandruff. It has predilections for such places as the junction of forehead and hairy scalp, the temples, ears, naso genial folds, around the mouth, intermammary region; interscapular region; axillæ; crurogenital regions; and the back of the hand, particularly between the metacarpals of the thumb and index finger. It is prone to show a yellow coloration, (due to increased fatty secretion,) tends to spread in a serpiginous manner, and is of three grades of severity, squamous, crusted, and moist or weeping.

The creeping mode of spreading, the effect of parasiticides, and the finding of microorganisms lead to a belief in a parasitic origin.

The diagnosis depends on the mode of spread, from the head downward, on the finding of scaly spots—outposts of the disease, and the choice of certain localities, the yellow color and serpiginous character.

Unna mentions the frequent appearance of seborrhœic eczema in cases of syphilis, causing an itching, serpiginuous eruption and calling for local as well as general treatment.

The author takes issue with Unna in regard to the secretion of fat by the sweatglands—he thinks this does not take place but that the fat comes from around the hair follicles, and bears no relation in quantity to the number of sweat glands. The vernix caseesa, also, he thinks due to the sebaceous and not to the sweat glands.

The paper is accompanied by some plates showing the microscopic conditions seen.

The observations confirm the view that seborrhœa is a disease of the sebaceous glands and also that of Unna—that dry seborrhœa is an inflammation of the skin.

Dr. Alexander Morton writes of "Eruption following the Use of Oil of Sandalwood."

He describes a case, a man twenty-five years old under treatment for a fresh attack of gonorrhœa by injection of solution of chloride of zinc and, interially, twenty drop doses of sandal oil in capsules, three or four times daily. The gonorrhœa improved rapidly, but in the third week of treatment there was a sudden eruption on the trunk and lower limbs.

The eruption was of dark red spots, many purpuric, about the size of a split pea. Many coalesced.

These spots were quite smooth and scarcely elevated. The eruption was fairly symmetrical, more abundantly on the back than front and on the extensor than the flexor surface of the legs. No subjective sensation, no complaint arthritic pains, no constitutional disturbance.

The drug was stopped, and in a few days the eruption disappeared without desquamation and leaving a very slight evanescent pigmentation.

There are many reasons for believing that sandal oil is not adulterated with copailia and the author gives a series of these, and also, though this eruption resembled in appearance some of those due to copailia, it was unaccompanied by itching and did not appear until the second week of treatment, while a copailia rash is to be looked for in about eight days.

Erichsen stands almost alone among English authorities who believed in gonorrhœal eruptions and those described by him might readily be syphilitic, as diagnostic appearances are not given and this may be said of the descriptions of most foreign writers.

The great necessity for recognizing a drug eruption is emphasized by one or two cases mentioned.

Dr. W. Dale James describes a case of "Glycosuria from Taking Thyroid Extract." The symptoms disappeared on stopping the use of the drug and adopting a diabetic diet.

Dr. S. G. Stafford Taylor describes "Two Fatal Cases of Pemphigus."

PERISCOPE.

IN CHARGE OF WM. E. PARKE, A.M., M. D.

MEDICINE.

Hydrastinine in Uterine Hemorrhage.

Gottschalk, (*Brooklyn Med. Jour.*), says hydrastinine may be employed:

1. First of all, in those uterine hemorrhages which are traceable to a pronounced congestion of the uterus. To these belong, above all, the often very profuse menorrhagias of spinsters, in whom there is no pathological change in the condition of the genitals. In some of these cases it is possible to obtain a permanent result, so that even after discontinuing the remedy the menstrual flow remains smaller.

2. Also in hemorrhages which have their pathological and anatomical cause in endometritis, hydrastinine will lessen the quantity of blood, but here, according to Gottschalk's experience, the action is only palliative, not being sufficient alone to cure the local cause of the trouble.

3. For prophylactic or intermenstrual use, hydrastinine is useful before or during the first returning profuse menstruation after an abrasion of the uterine mucosa. It is well known that this menstruation, occurring after six weeks is often very profuse. In the very cases where there was a great loss of blood before the operation, it is of great importance to prevent further profuse hemorrhage. This is possible if the treatment with hydrastinine is begun several days before the expected menstruation, and, if necessary, continued during the duration of the menstruation.

4. Menorrhagias caused by retroflexio uteri are best treated by correction of the malposition; but for cases of fixed retroflexion, where the reposition is not yet possible, hydrastinine is a commendable remedy.

5. Secondly, uterine hemorrhages, *i. e.* those caused by the changes of the adnexa and their surroundings—offer a large field for the successful use of hydrastinine. To these belong the menorrhagia and metrorrhagia with pyosalpinx, oophoritis, ovarian tumors and exudations. Of course the cause of the trouble is not influenced by the remedy.

6. Climacteric menorrhagias are much diminished by a faithfully carried out hydrastinine treatment.—*Canada Lancet.*

Treatment of Alcoholism by Strychnine Nitrate.

Breed concludes a paper in the *Medical News* of April 7, 1894, on this subject as follows:

1. That we have in this drug a remedy that actually, for a period as yet undetermined, removes the desire for alcoholic stimulation in the chronic inebriate, and that *without the least effort on his part.*

2. A remedy that removes the distress and gnawing at the epigastrium, so common upon the withdrawal of alcohol.

3. A remedy that tones up the nervous system, allays the insomnia, the flighty and other bad feelings in the head, the mental disturbances, and the tremulous agitation and uncertainty of voluntary motions due to the withdrawal of stimulants.

4. A remedy that brings back the appetite and general physical vigor in the body.

5. A remedy that temporarily transforms a wholly demoralized creature into a man.

6. A remedy that is of great value in acute attacks of alcoholism.

7. Incidently, a remedy that is an exceedingly good and safe heart-tonic.

8. More than all, a remedy that exerts a moral influence upon the patient, giving him what he had before wholly lost,—to wit, hope, enthusiasm, self-confidence, and courage, where before was dependency, abandonment, and despair; a steady, straightforward gaze, and a bright, youthful expression of the eye, which replaces the shamefaced, snakeing, apologetic air of total depravity of the chronic inebriate.

9. We have in the nitrate of strychnine not a remedy that will oblige a man to abstain from drink if he does not want to do so, and such subjects do not deserve one. From the results obtained by the gold cure, the silver-ash cure, the Keeley cure, etc., we may conclude that we have a remedy that is as efficient as any of these and much safer; a remedy, moreover, that is not secret, and can be used by men who know the action of drugs and can use them with discretion and safety to the patient.

Meat-Eating and Bad Temper.

Mrs. Ernest Hart, who accompanied her husband in his recent trip around the world, appears to come to the conclusion that meat-eating is bad for the temper. In the *Hospital* she says that in no country is home rendered so unhappy and life made so miserable by the ill-temper of those who are obliged to live together as in England. If we compare domestic life and manners in England with those of other countries where meat does not form such an integral article of diet, a notable improvement will be remarked. In less meat-eating France, urbanity is the rule of the home; in fish and rice-eating Japan, harsh words are unknown, and an equisite politeness to one another prevails even among the children who play together in the streets. In Japan I never heard rude, angry words spoken by any but Englishmen. I am strongly of opinion that the ill-temper of the English is caused in a great measure by a too abundant meat dietary combined with a sedentary life. The half-oxidized products of albumen circulating in the blood produce both mental and moral disturbances. The healthful thing to do is to lead an active and unselfish life, on a moderate diet, sufficient to maintain strength and not increase weight. —*Boston Medical and Surgical Journal.*

SURGERY.

Appendicitis.

Dr. J. Wm. White in *Theapeutic Gazette.*

SUMMARY:

1. The explanation of the great frequency of inflammation of the appendix is to be found in the following facts:

(*a*) It is a functionless structure of low vitality, removed from the direct fæcal current; it has a scanty mesentery so attached to both cæcum and ileum that it is easily stretched or twisted when they become distended; it derives its blood-supply through a single vessel, the calibre of which is seriously interferred with or altogether occluded by anything which produces dragging upon the mesentery.

(*b*) In addition, there is almost always present a micro-organism—the *bacterium coli commune*—capable of great virulence when there is constriction of the appendix or lesions of its mucous coat or of its parietes.

2. The symptoms in a case of mild catarrhal appendicitis—general abdominal pain, umbilical pain, localized pain and tenderness on pressure in the right iliac fossa, vomiting, moderate fever, and slightly-increased pulse-rate—cannot at present with any certainty be distinguished from the symptoms, apparently precisely identical, which mark the onset of a case destined to be of the very gravest type.

3. It must be determined by future experience whether or not operation in every case of appendicitis, as soon as the diagnosis is made, would be attended by a lower mortality than would waiting for more definite symptoms indicating unmistakably the need need of operative interference. At present such indication exists in every case if the onset is sudden and the symptoms markedly severe, and whenever in a mild case the symptoms are unrelieved at the end of forty-eight hours, or, *a fortiori*, if at that time they are growing worse.

4. It must be determined by future experience whether cases seen from the third to the sixth day, which present indications of the beginning circumscription of the disease by adhesions and which tend to the formation of localized abscesses, will do better with immediate operation with the risk of infecting the general peritoneal cavity, or with later operation when the circumscribing wall is stronger and less likely to be broken through. At present, operation is certainly indicated whenever a firm, slowly-forming, well-defined mass in the right iliac fossa is to be felt; or, on the other hand, when a sudden increase in the sharpness and the diffusion of the pain and tenderness points to perforation of the appendix or breaking down of the limiting adhesions.

5. In the beginning of general suppurative peritonitis, operation offers some hope of success. In the presence of general peritonitis with septic paresis of the intestines, operation has thus far been useless.

6. Recurrent appendicitis of mild type, like acute appendicitis, frequently results from digestive derangements. Several attacks may occur followed by entire and permanent recovery, but it is as yet impossible to differentiate these cases accurately from those which do not tend to spontaneous cure. Operation is certainly indicated whenever the attacks are very frequent.

7. Chronic relapsing appendicitis is characterized by the persistence of local symptoms during the intervals and by more or less failure of the general health. It usually indicates operation.

8. In either the recurrent or the chronic relapsing variety operation should be advised according to the following indications formulated by Treves: whenever (1) the attacks have been very numerous. (2) The attacks are increasing in frequency and severity. (3) The last attack has been so severe as to place the patient's life in considerable danger. (4) The constant relapses have reduced the patient to the condition of a chronic invalid, and have rendered him unfit to follow any occupation. (5) Owing to the persistence of certain local symptoms during the quiescent period, there is a probability that a collection of pus exists in or about the appendix.

HYGIENE.

The Question of Disinfection of Apartments.

Chamberland and Fernbach (*Revue Scientifique*) say: The disinfection of apartments that have been occupied by patients suffering from contagious diseases is of great importance. Experiments are being constantly made with the object of discovering a reliable disinfectant, free of destructive or noxious properties. While linen, clothing and bedding can be easily disinfected with steam, with or without pressure, the walls, ceiling and floor, are the great difficulty. Corrosive sublimate, besides being a dangerous poison, is not efficacious when the surfaces are not smooth. The essences, as shown by Ch. Chamberland are valuable antiseptics, but it requires several days before some pathogenic germs are destroyed. Peroxide of hydrogen acts better than ozone, and destroys the germs rapidly if applied with a spray, but it is expensive. From numerous experiments made on the bacillus subtilis, the aspergillus niger, the torula cerevesiæ, the typhoid bacillus, and others, Chamberland, one of the distinguished directors of the Pasteur Institute in Paris, and his collaborator, concludes that chloride of lime in the proportion of ten per cent., at a temperature of 40° to 50° C., is the best and cheapest disinfectant.—*N. Y. Therap. Rev.*

BACTERIOLOGY.

Antiseptic Properties of the Oil of Cinnamon.

Kyle (*Therap. Gaz.*) finds that in a strength of $\frac{1}{500}$ it prevents the growth of the germs suppuration and erysipelas after an exposure of not less than thirty minutes, those of tubercle, anthrax, tetanus and glanders require an exposure of at least two hours; typhoid fever between one and two hours, and Asiatic cholera from three to five hours. The effect produced upon the germs he believes to be

rather a suspension of activity than complete destruction, so that this cannot be regarded as a safe antiseptic for surgical work, though valuable for application to mucous membranes.

Germs in Agriculture.

M. Jean Danysz recently reported to the French Academy an ingenious method of ridding the country of small rodents which had become so numerous and destructive that it was impossible to produce any crop. Every acre of land furnished a home for thousands of these pests. The method adopted was to dissolve some gelatin cultures of pathogenic bacteria capable of producing an infectious disease in mice, then soaking a great number of small cubes of bread in this solution, and placing the bread near the holes occupied by the rodents, every day for three days in succession. Within two weeks after this method was adopted, scarcely a live mouse was to be found in the district treated. When the burrows of the rodents were opened, their galleries were found to be filled with dead mice.—*Molium Medicine.*

Bacilli Tuberculosis in Cigars.

Dr. Kerez (*Centralblatt fur Bacteriologie*), reports the result of experiments which he has been making for the purpose of determining the possibility of the communication of tuberculosis through the medium of cigars. It is a well known fact that cigar makers are in the habit of making the leaves adhere to the cigar by moistening them with saliva from their own mouths. The force of habit leads them to continue this practice, although in recent times manufactures provide their workmen with materials for the purpose indicated. Dr. Kerez made cigars by moistening the leaves with saliva known to contain tubercle bacilli. The cigars were then dried and packed away in boxes in the usual manner. It was found afterward, when the cigars were unrolled and the leaves washed in water, that the infusion thus obtained, having been injected in guinea pigs, produced consumption, clearly showing that cigars may thus be the means of communicating tubercle bacilli and giving rise to pulmonary disease.—*Journal of the Med. Sci.*

OBSTETRICS.

The Placenta in Uterine and Tubal Abortion.

Pilliet (*Progres Medical*), has studied two distinct cases of tubal abortion and compared them with many other reported instances of this condition. The chief characteristic of tubal abortion is its incompleteness. After the destruction or expulsion of the fœtus portions of placenta remain attached to the tube and continue to develop. The same occurs in many cases of early uterine abortion, hence placental polypi or tumors—"placentoma" or "deciduoma"—develop. Dropsical hydatidiform chorionic villi, representing an abortion several years past, have been removed from the uterus with the curette. But the parasitic remains of the placenta are far more commonly seen, if not constant, after tubal abortion. In tubal gestation ending in abortion small hemorrhages set in, then a free show, corresponding to the expulsion of part of the ovum. Slight oozing follows, then the tube fills gradually, and at last another considerable loss of blood occurs. The presence of a piece of placental tissue explains this phenomenon. When, therefore, after a loss of blood resembling in clinical history an abortion, a tube remains enlarged and tender, and, when uterine hemorrhages continue, without complete return of the tube to its normal proportions, tubal gestation, and incomplete abortion may be diagnosed. Hence an operation is indicated to anticipate the risks of intraperitoneal rupture. The persistence of portions of placenta after abortion appears easy to explain. At term the blood sinuses of the uterine tissue have widened and coalesced so as to form a single layer of blood between the maternal and the fœtal structures. Hence complete detachment of the placenta is easily effected. In abortion the above-named condition has not developed, detachment becoming more difficult. In tubal abortion the placenta becomes closely united to the tubal wall, which cannot undergo the complicated changes that occur in the uterine tissue in normal pregnancy.

ARMY AND NAVY.

CHANGES IN THE U. S. ARMY FROM JULY 7, 1894, to JULY 14, 1894.

Captain George McCreery, Assistant Surgeon, will be relieved from duty at Fort D. A. Russell, Wyoming, by the Commanding Officer at that post and will report for duty at Fort Washakie, Wyoming.

First Lieutenant Frank T. Meriwether, Assistant Surgeon, will be relieved from duty at Fort Logan, Colorado, by the Commanding Officer of that post and will report for duty at San Diego Barracks, California.

Major Augustus A. De Loffre, Surgeon U. S. Army, Fort Logan, Colorado, is granted three (3) months leave of absence, with permission to go beyond sea.

Captain James D. Glennan, Assistant Surgeon, now on leave of absence, will report without delay to the Commanding General, Department of the Missouri for temporary duty.

Major Egon A. Kœrper, Surgeon, granted leave of absence for one month on Surgeons Certificate of Disability.

The leave of absence for seven days, granted Captain Paul Clendenin, Assistant Surgeon, is extended twenty-three days.

NEWS AND MISCELLANY.

The St. Louis *Clinique* has passed into the hands of Dr. Emory Lanphear, Professor of Surgery in the College of Physicians and Surgeons. Dr. Lanphear will conduct the journal in the interests of that school, and of the medical profession of the West.

THE
MEDICAL AND SURGICAL REPORTER.

ORIGINAL ARTICLES.

INTERSTITIAL KERATITIS; ITS DIAGNOSIS AND TREATMENT.

E. W. STEVENS, M. D.,* Philadelphia, Pa.

The discussion of interstitial keratitis opens up a wide field interesting alike to the ophthalmic surgeon and the general practitioner, for apart from a consideration of the clinical features presented by it, a diagnostic significance has been attributed to the disease, namely, that its occurrence infallibly stamps the syphilitic inheritance of the patient.

A typical case of interstitial keratitis begins commonly with slight ciliary congestion and watering of one eye. In a few days a faint cloudiness is seen, beginning at the margin, sometimes at the centre of the cornea and extending over it. This haziness is situated in the true substance of the cornea, the epithelium is intact. In some instances the haze is seen to be made up of small circumscribed dots, occasionally cases are seen presenting one or two small dots as the only lesion. Gradually the opacity becomes more dense, and at an early date vision is usually greatly reduced. In from two to four weeks the cornea has generally passed into a condition of white haziness, looking like ground glass. Photophobia and pain are often moderate. Sometimes, however, they are severe. When the inflammation is at its height there is usually a zone of pericorneal hyperæmia, and even when the zone appears to be absent it may be readily produced by touching the eye or exposing it to light. Blood vessels often make their appearance in the deep and superficial parts of the cornea. They may require focal illumination for their detection, or the whole substance of the cornea may be red on account of the vast network of new vessels. Redness of the cornea is however uncommon. When situated in the deep parts of the cornea the scarlet hue of the vessels is toned down bythe hazy superficial layers through which they are seen, giving a dull reddish pink color (salmon patch of Hutchinson). An abundance of vessels in the cornea means a protracted case. There is little or no tendency to ulceration of the cornea, or to the formation of pus. Sometimes the disease is attended with iritis and inflammation of the deeper structures of the eye, evidence of which can seldom be noted through the hazy cornea. Rarely can the pupil be illuminated even in mild cases.

Both eyes are usually affected in interstitial keratitis. In Hutchinson's series of 102 cases, 91 were symmetrical. Usually an interval of a few weeks separates the onset in the two eyes. Rarely the interval is a year or more. The disease usually occurs between the ages of 8 and 15 years. Cases occurring as early as 18 months and as late as the 60th year have been reported. None of Mr. Hutchinson's cases were over twenty-six years. Early cases are usually mild. The disease may run its course for months or years and may terminate in recovery or a most

*Instructor in Diseases of the Eye, Philadelphia Polyclinic.

damaging opacity of the cornea. Rarely does the patient recover perfect vision, owing to the irregular astigmatism produced. Iritis occurring makes the prognosis more unfavorable. A favorable result is much influenced by the character of the case, which may be very mild throughout its whole course. Treatment does not greatly influence the outcome. When only one eye is affected treatment will not prevent the onset of the disease in the other eye.

Of great interest is the question of the relation of the disease to hereditary syphilis, and on this subject there is a wide difference of opinions. Mr. Hutchinson and Panas may be quoted as the most distinguished supporters of the two extreme views held upon this subject. In 1863, in a memoir on "Syphilitic Diseases of the Eye and Ear" (page 204), Mr. Hutchinson first enunciated the statement that interstitial keratitis is always a symptom of hereditary syphilis. That his views upon this question have undergone no changes is shown by his recent contributions, "Interstitial keratitis in its typical form is always a consequence of syphilis, and it is itself sufficient for the diagnosis," (Syphilis, London, 1887, page 75). Mr. Hutchinson also contends that interstitial keratisis is not a symptom of a cacheria produced by syphilis, but is caused by the virus acting directly on the tissue of the cornea. "The transmission of the disease in inheritance as well as in acquisition is always effected by the conveyance from person to person not of a tendency to disease but of a particular virus" (Syphilis, London, 1887, p. 71). "It is not the the state of health which syphilis may produce in the parent which he transmits to his offspring, but the poison itself" (Ibid, page 385).

Facilis princeps of English speaking syphilographers Mr. Hutchinson's opinions have always carried great weight, and so it has come to pass that the majority of English writers have concurred in his view, Nettleship, (Diseases of the eye, p. 142); Brudenell Carter, DeWecker, (Ocular Therapeutics, p. 124); Noyes, (Text Book Diseases of the Eye, 1890, p. 329); Fuchs, (Textbook, Ophthalmology); Macnamara, and many others have ranged themselves on this side. Among the most ardent supporters of Hutchinson's theory must be mentioned Dr. J. William White, of this city. Dr. White, in his comprehensive article on "Hereditary Syphilis" in Pepper's System of Medicine, p. 202, after carefully examining the clinical evidence upon this question maintains, "Interstitial Keratitis is a symptom of inherited syphilis, and the unmistakable presence of the former disease is sufficient proof of the existence of the latter."

On the other hand, it would appear that a majority of the authorities who have written upon this subject, while recognizing the important part which inherited syphilis plays in the production of interstitial keratitis, as first pointed out by Hutchinson, do not agree with him that in its typical form it is almost a consequence of syphilis, and is sufficient for the diagnosis; and who hold that while the disease is a symptom of a cachexia frequently produced by syphilis, it is often caused by other systemic diseases affecting nutrition, such as scrofula and rheumatism, each of which by its debilitating influence may give rise to a diathesis which favors the development of the disease. Panas, one of the most distinguished advocates of this view, says (Archives de l'Opthal, Vol. I., page 578) "hereditary syphilis is only one of the numerous causes of the exhaustion of constitution which leads to rickets and later on to interstitial keratitis," "Interstitial keratitis is a manifestation, '*de la misere organique*,' whatever its cause may be. Inherited syphilis may be one of its causes but it is neither the only one or even the most common" (page 580). This view has the weighty sanction of Schweiger (Handbook Ophthalmology, page 298). "Interstitial keratitis undoubtedly occurs in individuals absolutely free from syphilis. Mr. Hutchinson's view that this disease is to be regarded as a distinct consequence of congenital syphilis has not been generally adopted in Germany." Many other opthalmic surgeons have expressed themselves more or less strongly to the same effect, Saemisch, (Graefe & Saemisch's Handbook, Vol. IV., p. 264); Solberg Wells, (Diseases of the Eye, p. 138); Graefe, Manthuer, (Zeissl's Jahrbuck der Syphilis, 1875, p. 288); Oliver & Norris, (Text-book Ophthal, 1893, p. 333). Edward Jackson, "The most frequent cause is inherited syphilis, but it may depend upon other causes of malnutrition" (Essential Diseases Eye, p. 95).

Dr. Hayes Agnew says, "The disease (interstitial keratitis) is seldom seen independent of inherited constitutional vice. Either strumous or syphililic (Agnew's Surgery, Vol. III., p. 208).

The following table of statistics upon this question, compiled by Dr. Emil Gross, and quoted by Dr. Ogilvie in the *London Lancet* for 1893 (page 1438), is interesting as giving the percentage of cases showing hereditary syphilis:

NAME.	Number of Cases.	Percentage of Inherited Syphilis
Alexander	102	35.3
Aucke	100	61.0
Ayrs	12	8.3
Cohn	...	6.5
Davidson	...	20.0
Despagnet	119	14.2
Dietin	18	55.2
Giraud-Tenlon	30	46.6
Graefe	...	5.0
Haletnhoff	66	42.7
Horner	51	70.5
Iakouelena	63	57.1
Leplat	28	64.2
Michel	...	55.0
Nettleship	...	68.0
Parinand	32	96.7
Pfister	130	64.6
Saemisch	...	63.0
Sedan	34	32.3
Theobold	8	50.0
Trousseau	40	92 5
Wecker	...	66.0

The existence of interstitial keratitis in acquired syphilis is proved beyond doubt, cases having been recorded by many of the best and most competent observers as Alexander, Horner, Hirschberg, Haltenhoff, Michael, Hutchinson and others.

It would appear from an impartial consideration of the clinical evidence, that in the causation of interstitial keratitis, syphilis plays the most important part, but not the only part. Perhaps 60 per cent. are specific. The corneal affection is an important symptom of syphilis, but only to the same extent as are all the other symptoms of this polymorphous disease of which not one is pathognomonic, and tbe diagnosis of which "is to be attained rather by a careful appreciation of all the facts than by placing confidence in any one symptom," (Hutchinson, Syphilis, 1887.)

The treatment of interstitial keratitis is quickly summed up. Good hygiene, proper food and protection of the sensitive cornea by wearing smoked glasses. Instil morning and night into the conjunctival sac a few drops of a solution of atropine sulph, gr. ii to the ounce, with frequent bathing of the eye for a few minutes at a time with hot water. Small tonic doses of mercury may be given, but even in well marked syphilitic cases it is often doubtful if it does any good. On the other hand many cases are known in which mercurial treatment seemed to have an injurious effect on the corneal disease. This was first observed by Hutchinson himself. Cod liver oil or syrup of the iodide of iron should be given if indicated. All local applications as silver tannin, etc. always do harm. Brudenell Carter says some of the worst cases he has encountered had been aggravated by irritating local applications. When the acute stage is ended, the yellow oxide of mercury ointment may be employed with benefit to stimulate the absorbents in carrying off the remains of the opacity.

IN the *Berliner klinische Wochenschrift* (cried in the *Centralblatt fur Klinische Medicin*) Dr. P. Furbinger treats of the peanut as an article of food rich in albumin, of which it contains forty-seven per cent., together with nineteen per cent. of fat and non-nitrogenous extractive matters. He recommends the use of roasted peanuts in the form of soup or mush. On account of their cheapness, peanuts are recommended as a popular article of food, especially in poorhouses and the like; moreover, they are recommended as an artrcle of food for the corpulent, for diabetes, and for the subjects of kidney disease, in the last mentioned of which foods rich in animal albumin are to be avoided.

For Chilblains.

Dr. James R. Wood (*Amer. Med. Surg. Bulletin*) employs the following:

℞ Zinci oxidi 3j
Camphoræ pulv. .....
Myrrhæ pulv. .....
Opii pulv ..... āā gr. xxx
Adipis 3j
M.

AN ice poultice, made by thoroughly mixing together finely cracked ice, sawdust and salt, will be found to be an excellent application in supraorbital neuralgia, or in any similar painful affection, if the nerve be superficial. It may also be utilized to deaden the sensibility of the skin previous to opening abscesses, felons, buboes, removing small tumors, etc. It should be remembered that freezing may result from its continued application.--*Ex.*

THE TREATMENT OF TYPHOID FEVER.*

M. A. CLARK, A. M., M. D., Barnesville, Ga.

The first duty of the physician in the treatment of any disease is to pay strict attention to prophylaxis and hygiene. This is, especially applicable to the successful management of typhoid fever.

With proper attention to these, the majority of cases of typhoid fever will recover without any medicinal treatment. Hence, we should be very wary in making any decided claims for medicine. We do know, however, that there are remedies, which will not only mitigate the symptoms but also shorten the disease itself. Such being true, it is the duty of every physician to seek diligently for these remedies and to judiciously and faithfully apply them.

In this paper, I propose to set before you what seem to me to be the best of these remedies.

Before referring to the subject proper, allow me to say that I fully believe that this disease is due to some powerful germ, no doubt the bacillus of Eberth, which produces not only very marked lesions in the parts invaded, but also very decided nervous phenomena and great waste of the whole system. If we, then, can find some remedy that will check this dread germ in its ravages and destroy the poison it produces, we have found that remedy which will prove a most powerful adjuvant in the management of this disease. Our hope lies in the antiseptic treatment. In fact, it seems to me that this plan of treatment is *par excellence* the one from which we may hope to derive any decided results.

Henry claims best results from thymol; Rossbach and Wolff, from naphthalin; Pepper, from nitrate of silver; Thistle, from salol; and calomel is urged by others. All of these are no doubt good and well worthy of trial. Having had such good results from the use of another most powerful antiseptic, I beg to offer it as the one for the treatment of this disease, even though it falls short of the definition of an intestinal antiseptic as given by Bouchard—"It should be more or less insoluble and exert no toxic action on the organism." This remedy exerts no toxic action upon the system, but it is soluble being itself a solution.

I refer to hydrogen peroxide, which all will admit is a most potent antiseptic when locally applied. Seeing such excellent results from its local use, I ventured to test it as an internal antiseptic, believing that it would prove most effective. Having been rewarded with most wonderful results in the few cases in which I have used it, and feeling so sure of its continued effectiveness, I offer it to you for your consideration on this occasion.

If given at onset of the disease, it will not only mitigate the severe symptoms but will also check the disease itself. The tongue will rapidly clear off, tympanites will subside or not appear at all; the diarrhœa will diminish; no marked nervous phenomena will ensue, and the disease will spend its force with but comparatively little wear upon the system.

I give from 20 to 40 minims of some reliable 15 volume solution, preferably Marchand's, well diluted, every 2 or 3 hours till slight nausea is produced, and then every 4 or 6 hours till convalescence is fully established.

With its use from the beginning, I find no necessity for antipyretics, the temperature never rising sufficiently high to authorize their use. If, however, it becomes necessary to resort to some means of reducing the temperature, I prefer phenacetine in 5 gr. doses every 4 to 6 hours. The Brand method may work well in the hospital practice, but it can not be used effectually in ordinary private practice. If the phenacetine is followed by, or given with a mild stimulant and used only to reduce high temperature, there will be no unpleasant effects at all. I can not say so much for the other coal tars or even quinine.

I begin at the onset to attend carefully to the diet of my patients, striving to prevent all the waste possible by giving proper nourishment. Milk is by far the best diet. Given in small quantities and at frequent intervals it is usually well borne. If not well tolerated it may be peptonized and then given without ill effects. Hor-

*Read before Georgia State Medical Association, April, 1894.

lick's malted milk, beef tea and some reliable beef extract are usually easily assimilated and are valuable aids to the milk. Solid food is rigidly withheld.

Water should be given not only in connection with the medicines but also at frequent intervals whether called for by the patient or not. It is cooling and refreshing to the patient, aids in the elimination of poisons from the system by its diuretic effects upon the kidneys, and keeps up the normal amount of body fluids. It should be deemed one of the important factors in the treatment of this disease.

The mineral acids, inasmuch as they are aids to digestion, should be given in small doses, well diluted, three or four times daily. I prefer dilute nitrohydrochloric in 10 minim doses three times a day.

Alcohol should no longer be considered routine treatment, but should be used only when the symptoms absolutely indicate. Properly treated, few cases will require the frequent use of any alcoholic. When used it should be given most cautiously, as too much will cause unfavorable symptoms and is worse than not using at all.

Turpentine stupes or turpentine locally applied, may be used with benefit, whenever there is tympanites. I find it unnecessary when using peroxide of hydrogen.

If the diarrhœa is excessive, as many as six or eight stools in twenty-four hours, it should be controlled by nitrate of silver, bismuth, or some other astringent. I prefer bismuth subnitrate in 15 to 20 gr. doses, or salicylate in 5 to 10 gr. doses every two to four hours. I found no trouble with the diarrhœa, but, if it should become troublesome, I would employ in connection with the bismuth occasional enemeta of weak solutions of hydrogen peroxide, having found them very effective in the summer diarrhœas of children.

If the peroxide of hydrogen is given from the outset of the disease, the so-called typhoid phenomena, low muttering delirium, subsultus tendinum, picking at the bedclothes and so on, will not occur. If, however, I should be so unfortunate as to have to deal with them, I would rely solely upon the sedative dose of calomel, thirty grains. It will quiet such nervous phenomena when nothing else will, and, too, without any unpleasant effects upon the patient.

Other complications must be treated according to the usual methods. I believe, however, they will rarely occur, if this treatment is used from the beginning.

During convalescence, it is very essential that the patient be rigidly dieted. The liquid diet with a little broth, milk toast, soft boiled eggs, should be given till the third week of convalescence, and even then solid food should be used most cautiously.

I herewith submit two cases illustrative of the results of this treatment.

Jamie R., aged 10, family history good, previous health good. Had been sick with typhoid fever ten or twelve weeks and was in the beginning of the second relapse, so-called, when I was called in. Having been poorly nourished he was very anæmic and much emaciated. Saw him first in the afternoon. Temperature 106° F., pulse 140, weak and irregular, marked tympanites, pain and tenderness in right iliac region, very restless, slight delirium at intervals. Gave 3 grains of phenacetine with four teaspoonsful of brandy every four hours to reduce high temperature. Gave peroxide of hydrogen one ounce during the 24 hours. Milk at frequent intervals. In 36 hours temperature was under control, tympanites rapidly disappearing, delirium absent, patient comfortable and begging for bread. Continued the peroxide and nourishment. In one week temperature was normal and convalescence was well begun. Recovery was rapid and complete.

Annie L., aged 9, family history good, previous health good. Had just returned from a visit to place where there was an epidemic of typhoid fever. Had been sick a little more than a week, when I first saw her. Symptoms showed a case of typhoid fever of no mild type.

Began at once with 20 minims of hydrogen peroxide every three hours. Gave 5 minims of dilute nitro-hydrochloric acid three times daily. Milk in small quantities and frequently repeated. Used phenacetine and salol, 1½ grains each, to control restlessness and produce sleep during first two days. Afterwards continued the peroxide and nourishment. In less than three weeks temperature was normal and convalescence was fully established. Recovery was rapid and complete, there having been comparatively little exhaustion of strength and vitality.

ARTIFICIAL FEEDING AND THE CARE OF INFANTS.*

JOHN W. S. McCULLOUGH, M. D., Alliston, Ont.

The subject of the artificial feeding of infants is a most important one, and is becoming more so every day we live, because the number of children requiring it is rapidly increasing.

While it is an unfortunate thing for the child at the best of times to be deprived of Nature's form of food, it is no less a fact that circumstances often necessitate partial or complete feeding by hand,

Our profession has not, I think, given this subject the practical attention it merits. Too much latitude has been allowed the commercial greed of the makers of the various patent foods with which the market is stocked. The matter of infants' food and all the little details pertaining thereto, are usually left to the discretion of the nurse, who may be the most incompetent party in the world to judge in such matters, or else to the mother who, often young and inexperienced, feeds her child on pure cow's milk, or the same diluted with simple water or lime water. Not satisfied with this, for her baby usually does not thrive well upon it, she may add a daily allowance of boiled bread and milk or boiled biscuit. As a result the child has vomits or has diarrhœa. All the mothers of families in the neighborhood, with the most tender solicitude for the baby, assure the young mother that "Vomiting in a baby is a healthy sign." The mother soon is frightened into consulting her doctor. He, often without a great deal of thought to the matter, though he may tell her that such vomiting means too much, or an improper quality of food, may prescribe Nestles' Food, which is as good any of its class. It by no means nor often does well. It may suffice for a small child, but is never sufficient for a large one. If this evidence of simple indigestion were the worst result 'twere well, but the large infant mortality is directly traceable to improper feeding and, worse than all, so frequently is the miserable dyspeptic after-life.

These few reasons should amply suffice to lead us to inquire with the greatest care as to what should be the food of the infant, who must of necessity be fed on some substitute for the mother's milk. We should in such a case be at once able to recommend the best and to give proper instructions regarding its preparation, proper quantity, times of feeding, etc.

The best food is that one which first of all is satisfactory as regards quality. Then to meet with favor it must be simple of preparation, easily and cheaply procurable. A complicated plan may do for some people but with the majority it will suffer from neglect.

The patent foods, as I have already intimated, are not likely to be satisfactory as regards quality. They do not suit the varying ages of the child. They are expensive and not always to be depended upon.

The best food, and that which will continue to be most used, is one having for its basis cow's milk. Asses' and goat's milk approach the mother's more nearly in chemical composition, but they are not usually accessible. We must approximate the cow's milk by proper preparation to as near that of the mother's as possible.

A comparison of the two shows that

Cow's milk		Mother's milk
Acid	Reaction	Alkaline
13.2 per cent.	Solid	12-13 per cent.
4. per cent.	Fats.	3.4 per cent.
4. per cent.	Albuminoids	1-2 per cent.
4-5 per cent.	Sugar	.7 per cent.
.7 per cent.	Extractives	1-2 per cent.

So we see the chief differences between the two are in that cow's milk is acid in reaction, contains a little more fat, considerably more albuminoids and considerable less sugar.

The most important practical difference consists in the manner in which cow's milk coagulates in the stomach. It forms a tough curd unlike the flaky curd of mother's milk. This is indigestible and consequently ferments. It causes the painful flatulence, the vomiting and other well known troubles. Our success in treating cow's milk and feeding a child thereon will depend almost entirely on the manner in which we deal with the casein to prevent this tough curd from being formed.

Two methods are advised:

(1) By mechanically preventing the particles of casein from running together.

* Read before the Ontario Medical Association, June 6, 1894.

(2) By chemically preventing coagulation by the use of lime-water or other alkalies. This latter plan is entirely wrong because to accomplish its purpose would require a quantity equal to one-third of the meal. In the former method various kinds of mucilaginous fluids are recommended, such as acacia, gelatine, isinglass or tragacanth.

The plan I have followed for some two or three years is to use for this purpose barley-water made from the common grain of the farmer, or preferably the same crushed. It serves to mechanically separate the particles of curd and has some nutritious properties as well. The mucilaginous material comes largely from the inner surface of the hull. In Scotch or pearl barley this is lost.

I give the mother written or printed instructions as to this plan of feeding. I have her use boiled water for dilution, also cream as the child grows older, for I have found that especially where the supply of milk is not first-class, fat, instead of being in excess, is often deficient in quantity. The deficiency of sugar is made up by adding sugar of milk. The acidity has not, in my experience, been an important factor.

The plan of quantities and times of feeding according to the age of the child is as the following table indicates:

AGE OF CHILD.	COW'S MILK.	BARLEY WATER.	BOILED WATER.	CREAM.	SUGAR OF MILK.	INTERVALS OF FEEDING.
1st week.....	4 Drams.	4 Drams.	.....	.....	15 Grains.	Every 2 hours, night and day.
1st Month, rest of	6 "	5 "	.....	.....	15 "	Every 3 hours, from 4 a. m. till 10 p. m.
2nd Month.....	9 "	6 "	3 Drams.	3 Drams.	20 "	Every 2½ hours, from 4 a. m. till 10 p.m.
3rd Month.....	12 "	6 "	6 "	3 "	30 "	Every 3 hours, from 4 a. m. till 10 p. m.
4th Month.....	16 "	6 "	8 "	4 "	45 "	" " "
5th Month.....	18 "	6 "	10 "	5 "	1 Dram.	" " "
6th Month.....	20 "	6 "	10 "	5 "	1 "	" " "
7th Month.....	24 "	8 "	10 "	6 "	1 "	" " "
8th Month.....	26 "	8 "	10 "	6 "	1¼ "	" " "
9th Month.....	28 "	10 "	10 "	7 "	1½ "	" " "
10th Month.....	30 "	10 "	10 "	8 "	1¾ "	" " "
11th Month.....	32 "	10 "	10 "	8 "	1¾ "	" " "
12th Month.....	34 "	10 "	10 "	9 "	1¾ "	" " "

This plan gives, as you see, 6 hours rest to the mother and child. Often the child will sleep longer in the morning.

Regularity in feeding is a very important matter and should be rigidly insisted upon. At all times if you will, but especially when the external temperature reaches 60° F., it is best to sterilize the milk. Instruct the mother or nurse to do this by placing the bottles filled with milk in a large steamer over a pot of boiling water. From one-half to an hour's steaming will suffice to completely sterilize the milk. The bottles should then be tightly corked and set aside in a cool place ready for use. The barley-water is made by adding a cupful of barley whole or crushed to a quart of cold water. This is slowly boiled until reduced to about one pint when it is strained and set aside.

Care is necessary in the selection of sugar of milk. The cheaper kinds contain a large amount of flour and chalk.

The most convenient feeding bottle is an ordinary 6 or 8 oz. R. S. P. one, of which several should be in use at once. They are easily kept clean.

Conical black rubber teats which fit nicely over the neck of the bottle are the best. Never allow a tube of any kind to be used. Both teats and bottles when not in use should after thorough cleansing in boiling water, be placed to soak in a solution of soda bicarb. or a weak solution of permanganate of potash.

Never allow the child to suck the empty bottle, such fills the stomach with air.

A proper graduated glass measure which can be purchased cheaply in any drug-store, is both a necessity and a convenience. Measuring by means of a teaspoon is out of date and inaccurate.

A wire bracket over lamp or gas jet is

convenient, whereby the food may be warmed at night. The temperature of the food when given to the child should be about 95° F.

The quantities I have marked down are, of course, subject to variations according as the child is large or small.

The cream acts well in keeping the bowels regular. If not sufficient an occasional dose of fluid magnesia, P. D. & Co.'s cascara cordial, or minute doses of calomel repeated will do very well.

The usual bathing and due attention to cleanliness all help to a good result. Any excoriation of the buttocks should be prevented by careful toilet and the use of borated talcum. Unless the weather is extremely severe, the child properly protected, of course, should be out one or two hours a day, summer and winter. In summer when the weather is fine the child should be out most of the time. Good fresh air is essential for good sleep and good digestion.

I think this plan of feeding, meeting as it does the essentials of good quality, simplicity and accessibility which I laid down as the requisites of an artificial food, deserves a trial.

It is not by any means new. It is within the reach of everybody, is not complicated, and, in my hands at least, has given good results.

ADDENDA.

In the criticism which followed, the proprietary foods, consisting as they do chiefly of starch which a child under 7 months old cannot digest, were strongly condemned. I cordially agree with this and advise that they never be used nor prescribed,

The question was asked if pot-barley or Robinson's barley flour would not do better than grain barley. I do not believe so since they do not contain that which is essential to a good barley water, viz: the mucilaginous material which lies immediately inside the hull of the grain. This is *Gluten,* which is not starchy but a nitrogenous material composed of *fibrin*, *casein*, *gliadin* and *mucedin* (Foster's Dictionary).

Objection was taken to the quantity of food during first week, viz: 4 drams of milk, 4 drams of barley-water. I think this may be excessive in some cases where the child is small. My quantities are however, not absolute but more to serve as a guide that anything else. This is necessary. The physician ought to be a better judge as to quantities than any one else, and it would, to my mind, be foolish to give a child all it wants or more and allow it, as was suggested, to vomit the excess.

One gentleman objected to sterilization at the temperature of steam (212° F.) and said that extensive experiments in New York showed that babies fed on sterilized milk did not thrive. This is new to me, for sterilization has long been lauded to the skies. My only answer to this question is, that sterilization alone will not suffice. Often milk will, I believe, agree well when sterilization is not pursued, the more especially when the milk is produced at home and not, as city milk frequently is, carted over miles and miles of dusty roads or railway. In winter I may say that I have not insisted on sterilization and I have had good results. It has been suggested to me that the food and care of the cows should be looked after. This is an important point. The stable should be clean and airy and the food not too strong.

Just as the variation of food or improper food taken by the mother may induce digestive troubles in the baby, it can be no less true with regard to the source of the milk wherewith we prepare the artificial nourishment. I may add that whether or not my plan is correct in theory, I am amply satisfied that it is practically so. The best evidence of this is that babies thrive well on it, have few digestive troubles and are sure to attract attention by their hearty, lusty appearance.

The Removal of Warts.

TREATMENT OF STRANGULATED HERNIA.*

JOSEPH RANSOHOFF, M. D., F. R. C. S.†

A strangulated hernia if unrelieved, means death. It is almost equally true that if the strangulation is relieved early, recovery is the rule that ought to admit of few if any exceptions. The fatal cases of to-day are those of septic peritonitis, of gangrene, of contusion, paresis, and in the aged, pneumonia. The salient feature in the treatment of strangulation is the diagnosis. Given the following complex of symptoms, an irreducible tumor, hard and free of impulse in the site of an hernial aperture, accompanied by abdominal pain, obstipation, nausea and continuous vomiting, the diagnosis is indisputable. It is in the absence of or ill-pronounced development of one or many of these phenomena that the cause for doubt must be sought. The physical evidences of the hernia are often defective. The tumor may be small, too small to make a perceptible tumor, and palpable only in the depth of its canal. In the presence of a loose or irreducible hernia on the opposite side, the real seat of the strangulation is easily overlooked, Where a large and a small tumor are present, the probabilities of strangulation are *ceteris paribus*, greater in the smaller one. Furthermore it may be said that, inversely to the size of the hernia, are the acuteness of development and the severity of the symptoms.

The absence of communication between hernial sac and peritoneal cavity, as shown by the suppression of impulse and irreducibility, is an infalliable evidence of strangulation if the constriction is at the neck of the sac. In large hernias, strangulation by bands within the sac is common, in which cases there will be an impulse and the hernia may be partly reducible.

Torsion is a loop within the sac, occlusion within a diverticulum, of the sac, acute inflammation as of the appendix may occur without the suppression of abdominal impulse, and without increase of tension in the totality of the hernial protrusion. To an experienced surgeon, increased tension is a most important evidence of strangulation. Through gaseous distension of the intestine and serous transudation within the sac, a hernia after two days' strangulation may resemble a cystic tumor in its hardness and elasticity. The detection of a pedicle deep in an abdominal orifice, may avert an error. A subperitoneal lipoma or a cyst may conceal the hernia and complicate the diagnosis. Inflamed and retained testicles, and deep-seated lymphatic glands have been mistaken for strangulated hernia. The error is trivial. To err in the other direction has often proved fatal.

The symptom which in my judgment is most calculated to deceive is that of pain. Until adhesions form about the neck of the sac or within it, or unless manual efforts at reduction have been made, a strangulated hernia produces little or no pain at the side of the tumor. If present, it is overshadowed by the colicky pains of obstruction and the dragging pain of a fixed omentum or intestinal loop. It is felt chiefly in the umbilical region. Until the extra-peritoneal soft parts are involved in the inflammatory processes, a strangulated hernia is not very tender, except over the line of constriction.

Nearly every strangulated hernia is obstructed. Therefore, vomiting and obstipation are capital symptoms. They are not pathognomonic. In acute cases, vomiting is an initial symptom. It is copious, recurs at short intervals, and may in *foudroyante* cases, within twenty-four hours change to regurgitation of feculoid or fecal matter, with persistent hiccough. Such vomiting can not be mistaken. But even in acute cases the vomiting may be limited to one or two seizures in the twenty-four hours. Such vomiting, associated with diminished renal secretion and albuminuria, may readily be mistaken for that of uremia.

Obstipation is the rule in strangulated

* Abstract of a paper read in the Section on Surgery and Anatomy at the Forty-fifth Annual Meeting of the American Medical Association, held at San Francisco, June 5-8, 1894.

† Professor of Anatomy and Clinical Surgery, Medical College of Ohio, Cincinnati.

hernia. Lavage may remove the contents of the lower bowel. After that the intestine is impervious. The cases are very rare in which strangulation involves the omentum alone.

In the beginning the intestinal current may not be interfered with. With continued fixation of the gut, it soon becomes impermeable. This applies to strangulation of the appendix caught in a hernia, of which a number of cases have been recently reported, and to that form of hernia in which only a part of the circumference of the gut is involved.

There are yet other cases of hernial obstruction in which the diagnosis can not be made in one or two days. They occur in the large irreducible scrotal hernias of the aged. There are present retardation only of the onflow of the intestinal contents, slight colicky pain, little or no vomiting, recurrent constipation. Gradually the bowel is distended to a point beyond which the rings can not be made to yield. Then ensues strangulation as in the acute cases. One or two weeks may pass before the latter makes itself manifest.

Cases will occur in which doubt can not be dissipated. The prudent and wise surgeon will deal with all these as cases of strangulation.

In the treatment of strangulated hernia, only two methods can claim consideration: 1, taxis; 2, operative interference.

TAXIS.

The indications for taxis are few; the contra-indications many. Taxis should be restricted to the subacute obstructions of old hernias. The smaller the hernia and the acuter the symptoms, the less is taxis indicated; never in these cases after the first twenty-four hours of strangulation.

The bowel may be irrepairably damaged before this, but not often. Gangrene may be present without the usual evidences thereof, such as local edema and redness, great tympanites, rapid and feeble pulse, albuminuria. To consider the absence of any or all of these symptoms as indication for taxis, means enlarging the mortality from strangulated hernia.

Should the effort at taxis be successful which, perhaps fortunately, in the class of cases under consideration it rarely can be, it is so at the risk of returning to the abdominal cavity a loop of intestine doubtful as to viability, or with adherent limbs, and a hernial fluid ready to infect the peritoneum. Every effort at taxis is a confusion of the strangulated intestine. The blood-tinged hernial fluid is an evidence thereof. In intra-abdominal strangulation it is never encountered. Rents of the peritoneal coat of the distended intestine, the dread of the surgeon in laparotomy for obstruction, are none the less likely to occur because the bowel is manipulated under the soft parts and through the medium of a water-pad.

When reduction by taxis is indicated, it should be done under full anæsthesia. The absolute relaxation thereby obtained is doubtless responsible for many of the successes of taxis. A time limit to the manipulation has been given by many. Two unskilled hands can do more harm with taxis in twenty seconds than a careful operator will do in twenty minutes. Forced taxis is an abomination which has been expunged from surgical practice. It has been my fortune to see but one case of reduction *en masse*. The efforts of taxis should be gentle, continuous, and gradually increasing in force. Lateral pressure and gentle traction upon the neck of the sac may, by straightening the bend of the gut at the point of constriction, open a passage for the escape of its contents and thus be the immediate precursor of a reduction.

Taxis should be resorted to but once. When it fails, herniotomy can not be too soon performed.

KELOTOMY.

An operation for strangulation is, *per se*, not dangerous. The measure of its gravity is formulated by the condition of the parts and of the patient at the time of operation. I have had thirty-seven operations for strangulated hernia, in every case but one. Of these, six ended in death, two from gangrene and peritonitis, one from pneumonia in a man of 70, one from heart failure in a woman with aortic regurgitation, and one through an error in judgment in adding the radical to the relief operation in a large scrotal hernia. In the sixth case, laparotomy was performed for reduction *en masse*. The intestine, which seemed viable at the time of opertion by lamplight, gave way on the fifth day. With my present knowledge the deaths from heart failure and pneumonia

might have been averted, by substituting cocaine for general anæsthesia, since in neither patient could it have been a question of radical operation. In a case recently seen, I made the relief operation, removing a mass of omentum the size of a walnut, and returned the intestine without inflicting enough suffering to elicit a moan. The patient was 68 years of age and the subject of cardiac asthma.

From the foregoing limited experience, the conclusion is justified that in an otherwise healthy individual, death does not follow herniotomy, except as a consequence of grave changes in the hernial contents or within the abdominal cavity. The full statistics of Hagedorn of 170 operations fully bears out this view. It includes cases treated between 1883 and 1890. The general mortality was 14 per cent. The death rate was *nil* in cases in which the large intestine was involved; 48 per cent. in cases where the small intestine and omentum were unchanged; from 22 to 48 per cent. in cases where it was ecchymotic or suspected of gangrene. These results are a vast improvement on those given by Benno Schmidt, Rose and authorities of Great Britain a few years before, according to which the mortality varied from 25 to 48 per cent. Thus is negatived the view that the modern methods of wound treatment have not influenced the mortality of operations for strangulated hernia. As operations are performed earlier, and larger experience improves the methods of dealing with the grave complications, the mortality will be doubtless still further reduced.

OPERATION.

Except in the hernias of infants and in the large hernias of the aged, and then only when the constriction is known to be at the neck of the sac, the incision should be ample. An utter disregard of the anatomic tunics will facilitate procedures. There must be no enucleation until the sac proper has been reached. To reorganize this will sometimes embarrass an experienced operator. When thickened and covered by pendulous masses of fat it may greatly resemble a part of the colon. In acute hernias containing a considerable sanguinolent fluid, the resemblance to a discolored intestine is very great. The presence of ramifying vessels in the sac is distinguishing. So long as there is a doubt, it is quite certain that it is *not* the bowel which is exposed. In very rare cases there may be no sac under the line of incision, an uncovered portion of the large bowel or of the bladder presenting. An exploratory opening such as would naturally be made into the sac as ordinarily found, would while elucidating the relations, be far from being a serious mishap, if it involved the bowel.

Is the sac to be opened? This question has been affirmatively settled for all times, if not for all cases. In every case in which the radical operation is to be performed, in which there is the least doubt as to the site of the constriction or the condition of the hernial contents, and always before the constriction is relieved, the sac must be opened; the constricting ring to be divided from within. In the hernias of very young children, where the surroundings might make the aseptic course uncertain, and in the large obstructed hernias of subacute course as seen in the aged in whom a confinement of two weeks might be serious, an external herniotomy is doubtless justifiable. Although I have seen a number of cases in which it seemed applicable, I have never performed one, nor is it probable that I shall. An irrespressible anxiety to see the condition of the hernial contents impels me to what was known as the greater procedure of internal herniotomy. The division of the stricture is always a most delicate operation, in which the hernia knife of Cooper is almost indispensible, the finger serving as a guide. Save in the very tightest strangulations, the intestines are readily displaced to permit the nicking at one or several points of the constricting band. To avert the danger of wounding the intestine, the constriction can be divided from without. In inguinal hernia it is feasible. In femoral hernia it ought not to be practiced, since it entails the division of the crural arch.

The constriction relieved, the hernial contents often have a tendency at once to slip into the abdominal cavity. This is to be prevented, for no intestine is to be returned until it has been thoroughly inspected below, at, and for some distance beyond the line of constriction. In hernias which have been irreducible from adherent omentum, it may be difficult to find the strangulated intestine. Often it is small. In not a few cases the intestine

can not be properly exposed until the adherent and thickened omentum has been excised, since, as a rule, it can not be returned, it might as well be radically treated first as last. In dealing with the omentum, too much tissue should not be included in the ligature; this should be tightly drawn, care being taken that in the necessary manipulation the thin-walled veins are not torn. After thorough disinfection, the omental stump should always be returned into the abdominal cavity and not be permitted to remain near or within the hernial ring. I have seen one internal strangulation consequent on the fixation of an omentum to the internal ring, after a radical cure had been effected by truss.

Hernias in which there is obstruction without strangulation are generally dry. The coils of intestine are reddened, covered often with fibrinous flakes, and often adherent to each other and to the sac wall. Such adhesions should always be severed, lest after reduction the obstruction continue. The greatest care is necessary in severing the adhesions which have formed within the neck of the sac. They must be looked upon as the barrier to peritoneal invasion from an ulcerated bowel. Even with the greatest care, a rent may be made here as the bowel is drawn into the wound. This accident happened to me during the winter before my class.

There are few things more beautiful to the surgical eye than the fast changing colors of a tightly strangulated intestine, relieved of its constriction. Within a few minutes, dark brown or even black, in turn becomes chocolate, purple, dark red, and pink before the intestine is normal. The contained gases pass on, the constriction groove becomes shallower and while you observe, peritalsis may be reestablished. Such an intestine can be returned with safety Here two things are to be remembered: 1, it is as unsafe to return a distended gut to the abdomen after herniotomy as after abdominal section; and 2, that false reductions can be made after an operation quite as easily as after taxis. The absence of the gut from diverticula of the sac, which may be present between the musculo-fascial planes or in front of the peritoneum, must be established by the finger within the belly cavity before the reduction of the hernia can be said to be assured. With a free severance of adhesions about the neck of the sac, a mass reduction is not possible after herniotomy. When complications such as these follow herniotomy or taxis, the opening of the abdomen is justifiable. In no ordinary strangulated hernia, however, is hernioceliotomy a proper procedure.

Introduced as early as 1590 by Rosset and in 1723 by Cheselden, this chimera was almost forgotten until Mr. Tait made an effort to revive it in a paper before the British Medical Association, in 1891. Possibly of service for the radical relief, for reasons almost obvious it can have no place among procedures for strangulated hernia.

The most important question entering into the treatment of this subject is what to do with gangrenous hernia. Shall the constricting ring be divided? The theory was long advocated, and recently again promoted by Banks, that the constriction ring should ordinarily not be divided in gangrenous hernias, on the ground that it has the development of general peritonitis. By the constriction the septic products of a hernia may be isolated for a time. But the peritonitis develops from within, and that without the direct implication of the intestine. In a case of gangrenous hernia which contained only omentum, death resulted from general peritonitis. Just beyond the neck of the sac was the colon fixed by the adherent omentum, and its wall rendered paretic through traction, was unable to resist the passage through it of organisms fatal to the peritoneum.

Gangrene of the omentum is rare. Its safety is found in the ease with which it forms adhesions to the sac wall, through which it then receives its nutrition. The case alluded to is the only one I have seen. Benno Schmidt questions altogether the existence of primary strangulation of the omentum. Of Hagidan's 170 cases, gangrenous omentum was only once the sole occupant of the sac. I have found reports of two other cases: One from Heidelburg; the other of W. H. Bennett, of St. George's Hospital. There is but one opinion as to the management of gangrenous omentum. Excision after ligation in healthy tissue, and return to the abdomen, generally ends in recovery unless peritonitis already exists. The three cases quoted all recovered, although

in each the radical operation followed that for strangulation.

When gangrene involves the intestine, the solution of the problem is far less easy. Since Ramdohr first successfully resected the gut for hernia in 1727, the possible success of primary excision has been conceded.

Of recoveries there have been many. But the measure, however ideal, has never gained firm footing among surgical procedures. This in face of the fact that the results from the alternative measure, that of the formation of an artificial anus, have been most deplorable. Recently Poulsen reports twenty-nine cases, with but four recoveries. Of thirty-five cases as treated at St. Bartholomew's, four were saved (*British Medical Journal*, June, 1891, i., p. 701.) Certain is it that all cases should not be treated alike, and that every case ought to be considered with reference, first to the condition of the intestine and its environments, and second to the probability of the patient to bear the shock of a prolonged operation.

A stragulation affects the gut either along the line of constriction, or at some or all points of the coil involved, or in the course of the intestine for a varying distance above the point of constriction. Where the constricting band binds the gut, a well-marked groove is made by direct pressure. The constriction, tight enough to occlude the caliber of the bowel, may not interfere with its vascular supply. If gangrene results it will be from pressure at the bottom of the groove and limited in extent. Except for the usually small ulcer in the constriction groove, the gut above and below may be normal in appearance. In the fruitless effort of nature to protect the general peritoneum, adhesions are quickly formed between bowel and neck of sac. In the attempt to sever these, the fragile wall of the bowel tears along the line of constriction. Doubtless many cases of this kind occur, the fecal outpour taking place at the time of the operation. To avoid this it might be wise to follow the practice of Mikulicz, who in every case of suspected gangrene opens the rings from within the belly cavity, thus making a laparokelotomy which permits, as he thinks, thorough isolation by gauze of the infected area. The difficulty appears in the fact that pressure gangrene limited to the furrow and made by the constricting band is not always easily recognized. Fortunately the tissues about it, whether torn by manipulation or not, are in a fair condition for partial excision and lateral suture, by which the patient may be saved the perils and annoyance of an artificial anus. Krumm reports such a case successfully treated, and Barette three, of pressure gangrene successfully managed in the same manner. In such a case the gangrenous area may profitably be inverted and the contiguous parts sutured in a horizontal fold. In the case of rupture appended, the aperture was treated as a gunshot wound, sutured, and the coil returned to the abdomen, but anchored for forty-eight hours to the wound by a catgut suture through its mesentery.

In some cases the force of strangulation, although influencing the circulation of the whole knuckle, appears to affect most seriously its central part and at a point farthest removed from the mesentery. It is clear that if in such a case excision were to be done, it could only be beyond the limits of constriction. The cyanotic gut about the really gangrenous center would ill support a suture. Let alone it will recover. The handling incident to suture might easily prevent it. Furthermore, in cases of this nature the gangrene is often more extensive than is apparent. Beginning generally in the mucosa, the serous tissue is the last, and therefore least affected. The fixation of the gangrenous area in the bottom of the wound, relying on nature to make the anus preternaturalis, appears to me sound judgment. The data on which this view is based differ from those which militate against the formation of a fecal fistula when the gut is gangrenous in its entirety.

First and foremost, the caliber of the gut remains patent, and death from inanition is rendered impossible. Again, the fistula which results will probably be small, and close in a few weeks or months without operative interference.

When gangrene involves the entire strangulated knuckle the appearances are sufficiently characteristic. Chocolate of dark slate-colored, denuded in patches of its peritoneum, covered with flakes of lymph and in a collapsed condition, it fails to react to mechanical or chemical irritation. The odor is feted before perforation has taken place. When the strangulation has been very acute, the changes in

and about the hernial sac need not be very marked. After the escape of a varying amount of turbid bloody fluid from the sac, the latter appears of a bright or dusky red, minus the glistening appearance of the normal serosa. When it is of older date, one after another of the hernial coverings are involved in the inflammation. They are welded together, in turn to break down. A fecal abscess is the result.

The most serious and far-reaching changes in gangrenous hernia are often found in the afferent portion. They may be said to involve its caliber, its nutrition, its contents and the peritoneum singly or together. Although long recognized, the dangers inherent in this part of the intestine have recently been strongly brought forward by Beneke. Above the constriction there is always some dilatation with more or less paresis and congestion of the intestinal wall. It may be dark in color and edematous from venous stasis. Possibly from the same cause its mucous lining secretes abnormally, and as a result, at times, enormous accumulations of fluid are found—according to Mikulicz from one to three quarts. This forms an excellent culture medium for bacteria and in the process of putrescence, toxines are formed, the absorption of which doubtless accounts for many deaths under the mask of acute sepsis from strangulated hernia before peritonitis has developed. The disintegration of this fluid gives rise to a fecal odor irrespective of the site of the constriction, and it is this fluid forced into the stomach and thence regurgitated that is so ofoten mistaken for fecal vomite.—(Mikulicz.) Furthermore the wall of a paretic and congested gut has no power to resist the pathogenic organisms which it incloses. Far above the constriction, hemorrhagic infiltrations, diphtheritic-like deposits on, or ulceration of the mucous membrane may ensue. This is far more liable to such necrotic changes than the outer tunics and there is no way of knowing how far the process has extended. In one of Kocher's cases the gangrene extended four inches, and in one of Tændler's six inches above the suture line. In a case not submitted to operation, the diphtheritic deposits were found six feet above the constriction.

When death follows hernia, the symptoms of peritonitis are rarely absent. In the majority of cases, even in gangrene, there is no perforation within the abdomen, and the course of the peritoneal infection must have been through the microscopically intact gut. That it may occur where the gut does not enter into the hernia has already been seen. It has long been known through Nepveu's investigations that the fluid transudate in a hernial sac is rich in pathogenic organisms before gangrene has developed. Benneke has recently shown that the bacteria readily pass through the wall of the paretic bowel and produce diffuse peritoneal infection. On microscopic sections he was enabled to trace their progress through the intestinal wall. (Before the French Surgical Congress, Clado has recently made similar demonstrations.) From these sources metastic infection in remote organs may ensue. The process is like that seen in other morbid conditions of the intestine; notably in typhoid fever and appendicitis, where peritonitis developes without actual perforation.

Equally important with the local, is the general condition of the subject of a gangrenous hernia in determining the plan of procedure. When delay has brought the patient to the verge of collapse, when even the shock from prolonged anæsthesia cannot be ventured, *that* must be done which most readily gives relief to the strangulation. It may be the opening of a fecal abscess, the division of the stricture, or the rapid fixation of the gut in the wound. Whatever the procedure adopted in the condition indicated, the result will probably be the same—death within a few hours or days.

In most cases, however, the condition is less deplorable and evidently tolerant of a somewhat prolonged operation. It is in this class that choice must be made between the establishment of an artificial anus, and resection of the bowel with immediate suture of the divided ends.

Authorities are at variance as to the value of the two proceedures. In England, Baker, MacCormac, Banks and Treves decidedly oppose the greater operation of resection. In this country the same opinions have been held, unless they have been recently influenced by the reports of successful cases of excision by McCosh, Richardson, Dawbarn and others. In Germany, Kocher's and Czerny's first

successes were followed by many failures which frustrated the natural desire of surgeons to make primary incision the normal procedure in gangrenous hernia. Finally Reidel's critical review of the statistics in 1883 made it appear that the preferable primary operation was enterostomy, to be followed by a second operation for the closure of the preternatural opening. From the first, Kocher has remained steadfast to the ideal operation, and in Mikulicz he has recently found a most able supporter.

The advantages and disadvantages of the two procedures are almost apparant. If primary resection is successful, the patient is well in from four to six weeks. If an artificial anus is successfully established, a second operation of a very serious nature must follow. The artificial orifice is as large as the bowel, and the mucous membrane is prone to prolapse. Such an opening never closes spontaneously.

While in a considerable number of cases the enterotome of Dupuytren might be successfully applied with the low morality of 5 per cent. (Korte), it will fail in many cases and be absolutely inapplicable in others. Again, according to Dupuytren, it should not be used for two or three months after the primary operation. It is during this interval that the greatest danger from artificial anus is encountered, that from progressive inanition. Recently Poulsen has used it twelve and even nine days after the first operation.

It has not yet been established how much of the intestinal canal is essential to the maintenance of nutrition, but where the fistula is above the mid-part of the ileum, rapid emaciation and death follow before any secondary procedure for closing it can be practiced. McCosh does not overrate the argument of statistics in the statement that the death rate of all cases in which an artificial anus is made, including the operations for its relief, is 50 per cent. The danger from secondary resection and enterorrhaphy is very considerable. Haenel mentions forty-three cases, with sixteen deaths and two failures.

To be successful, the artificial anus must be established in healthy bowel, else the dangers inherent in the afferent portion will not be removed nor will a free outflow from the intestine be secured. The only advantages therefore which can be claimed for this method are the rapidity with which it can be performed and the slight technical skill required in its performance. A further advantage is supposed to exist in the lesser danger connected with this, as compared with the major procedure of immediate resection.

There is hardly a subject in surgery concerning which statistics are so much at variance as are those relating to gangrenous hernia. According to Korte, of 111 cases treated by enterostomy, eleven ended fatally. Herman (quoted by Haenel) mentions eighty-three cases with seven deaths. On the other hand, Weil reports fifteen cases with thirteen deaths. Benno Schmidt places the mortality at 85.5 per cent. for the formation of the artificial anus, as against 71.1 per cent. for primary resection.

F. A. Southern, Surgeon to the Manchester Royal Infirmary, recently reports eighty-five cases of herniotomy with nine cases of gangrene. All of the latter died. In six, an artificial anus was made; in three, primary excision.

If statistics are of any value in solving the relative merits of enterostomy and primary excision, it is evident that the reports of scattered cases are far less weighty than such from a few and skilled operators, and from hospital records where nothing is concealed. Such a tabulation has recently been made by Mikulicz from seven large clinics of Germany and Switzerland. Of 168 cases of gangrenous hernia, 109 died. Of ninety-four in which an artificial anus was made, seventy-two died; mortality, 76 per cent. Of sixty-eight primary excisions, thirty-two, or 47.1 per cent. died. Of six intermediary resections, five died. It would appear from this that the mortality of primary excision is very much less than that of the lesser operation. But this can be accounted for by the certainty that the latter was often used as a last measure in conditions approaching collapse, and therefore precluding the major operation.

These statistics practically coincide with the very extensive and recent tabulation of H. P. Zeidler, of St. Petersburg. Of 289 cases in which primary excision was performed, 142, or 49.13 per cent. died. Of 287 cases in which an artificial anus was established, 213, or 74.22 per cent. died. This is an increase in the mortality, of 25 per cent. In the group of cases of artificial anus there were 5.55 per cent.

more of cases hopeless from the beginning than in the group of primary resections. This still leaves 17 per cent. of cases which might probably have been saved by primary excision.—(*Cent. f. Chir.* 1893, p. 62).

The advantages of primary resection are patent. Its disadvantages are, the time required for its performance and the danger of peritonitis from imperfect technique. In a measure both can be overcome. The first of these is probably grossly exaggerated. With separation of the mesentery and its closure by suture, to be followed by the continuous Lembert-Czerny suture by lateral anastomosis, or by the use of button or potato plates, not more than half an hour at most should be required for the enterorrhaphy. Complicated clamps, a separate row of stitches for mucous and serous tunics, interrupted sutures unnecessarily waste time. When the continuous suture is used and appears weak at points, a few supplementary stitches can easily be taken. Suturing the mesentery brings the intestinal ends naturally together and gives assurance that the most treacherous part of the suture, that near the mesentery, can be properly applied. The second danger is from injudicious selection of the lines for suture. As elsewhere in gangrenous processes, the danger lies rather in removing too little than too much. If Kocher excised five and Koeberle six feet of intestine, a few inches more or less can not be important. In acute cases, where the caliber of the gut has not been long occluded, and koproöstasis is little, if at all developed, an inch or two on each side of the constriction groove will probably bring the suture line in healthy tissue. Where the mesentery has not been included in the strangulation, the same favorable conditions may be expected. Where, however, much dilatation of the afferent gut exists, its thorough evacuation should precede the enterorrhaphy. After hernia, as after laparotomy for obstruction, it is fatal to return a distended gut to the abdomen. The further danger, that of septic infection of the peritoneum, can in a large measure be reduced by thorough irrigation of the sac before suturing; by careful handling of the gangrenous gut without the wound, meanwhile protecting the peritoneum by gauze packing. Finally, the sutured intestine should be left just within the abdominal cavity and a radical cure should not be attempted. Mikulicz, whose success surpasses that of any other operator—twenty-one cases with fourteen recoveries—insists on the open treatment of these cases. Should fecal extravasation ensue from defective suture or other cause, it would naturally turn towards the wound, whereby the danger of general peritonitis would be largely averted. For from two to five days after the operation the sutured intestine remains where it is placed within the abdomen, and after that length of time the development of peritonitis is not probable. To hasten the process of wound repair, deep and superficial sutures might be drawn through the wound margins and kept over the gauze packing, to be tightened without anæsthesia after the danger line has been passed.

Between the extreme measures considered, others looking toward a compromise have recently been brought forward by a number of surgeons. Among these are the intermediary, excision and suture of Riedel. The artificial anus is established in the usual way. After twenty-four or forty-eight hours the edges of the intestine are vivified and united by suture. In 1882 Bouilly suggested excision and suture, the latter being purposely made imperfect at one point to guide the fecal extravasation. To avert the danger from imperfect suture, Hahn follows the kelotomy with a median laparotomy. Through this wound he brings the divided ends of the bowel, thoroughly protecting the abdomen against infection by packing them in gauze. When the suture is completed, the closed knuckle is kept in the wound between gauze splints until union is assured. The competency of the suture is certain after twenty-four hours, when the bowel is returned to the abdomen and the external wound closed. It is difficult to understand why the same procedure should not be carried out in the inguinal herniotomy wound. Nevertheless, Hahn has had two successes with it, and in a third, reported by Kutschera, the result was equally satisfactory.

To overcome the danger from death from inanition, Helferich has recently combined enterostomy with an intestinal anastomosis above the constriction furrows. By this method two courses are open to the intestinal circulation, and the

closure of the artificial anus is greatly facilitated. The operation was done in two cases, one of which was successful, the fecal fistula closing spontaneously.

There is yet another class of cases in which the condition of the bowel is such that whereas gangrene is not yet present, it might through subsequent necrosis cause death if returned to the abdomen. Such a knuckle is a menace. Who has not seen it? Especially if operating by light, both artificial and bad. A bowel that is not at all doubtful in appearance will at times repay the trust placed in it by a perforation. Among ninety-six deaths after herniotomy, it was in twenty-six cases the result of returning to the abdomen intestine which subsequently perforated. In Hagedorn's clinic three deaths out of fifteen resulted in the same way. To return doubtful intestine is unnecessarily jeopardizing life. To treat such intestine as radically as bowel already gangrenous is an extreme measure, not to be advocated. Fortunately the intestine can be retained in the wound for a number of days in gauze packing or by sutures. When its viability has been established, it is an easy matter to return it to the abdomen. Graefe recently reported a successful case in which the intestine was so retained for five days before replacing it. Should the dread of adhesion be feared, the intestine might be retained just within the abdomen by fixation sutures or by gauze. In the event of gangrene, the fecal extravasation would course toward the external wound.

When in 1880 Czerny reported his first case of primary excision for gangrene, he believed that the operation would not displace the older operation of enterostomy. Although the last four years have brought forward success after success from primary resection, the dictum of Czerny still holds good. Each operation has its proper field. The boundary lines are becoming more clearly defined. Nevertheless, it must always remain for the judgment and tact of the surgeon, as individual cases arise, to determine the proper procedure to be adopted. In operative surgery, as elsewhere, the ideal should be sought. This would make primary excision the normal procedure in gangrenous hernia, and only cogent reasons should cause the operator to refrain from striving for the ideal.—*J. A. M. A.*

AUTHENTIC REPORT OF THE ASSASSINATION, OPERATION AND DEATH OF CARNOT, THE PRESIDENT OF THE FRENCH REPUBLIC.*

PROF. A. PONCET, LYONS, FRANCE.
[THE ATTENDING SURGEON.]

M. Carnot, the President of the French Republic, was assassinated the 24th of June, at about a quarter after nine, in the evening. Scarcely had he taken a place in the carriage which was to conduct him to the Grand Theatre of Lyons when he was stabbed with a poignard. In the same carriage there were, at his left, General Borius; opposite to him, Professor Gailleton, mayor of the city, who had at his side General Voisin, the military governor. The deed was done so quickly that one would have thought that either a petition or a bouquet had been thrown into the carriage. The President threw his body slightly backwards, rather with a look of disgust on his face than pain or fear. Those about him thought at the first moment, that some dirty object had been thrown at him. The President immediately carried his hand to the injured spot and thrusting it between his shirt front and undershirt, he withdrew it, covered with blood and exclaimed: "I am wounded". At the same instant his head fell backwards and he lost consciousness. Prof. Gailleton immediately cared for the President and the carriage turned and, at this monent, a few seconds after the stabbing had been done, I saw M. Carnot. He lay limp in the carriage, his arms extended inertly alongside of his body and his head thrown backwards. His face was frightfully pale, his eyelids half

*Translated from *La Semaine Medicale*, No. 39, 1894, by F. H. Pritchard, M. D.

closed, his eyes glassy, and, if now and then slight groans had not been audible one would have thought that all was over. In the midst of the great throng, the cries of the crowd and the noise of the carriage and the escort, it was impossible to gain an idea of either the state of his heart or respiration. His hands were cold and I was unable to distinguish any pulse. The collapse was so great that we feared his death at any moment. I removed the clothing that encumbered his breast, at the same time trying to obtain an idea of the seat and extent of the wound. Guided by the blood that colored the bosom of his shirt we easily discovered on the right side, at about three centimetres from the ensiform cartilage and beneath the corresponding border of the ribs, a wound twenty to twenty-five millimetres in length, slightly oblique, following the margins of the rib and apparently made with a cutting instrument. The quantity of blood that had been lost, to judge from the soaked garments, might be placed at about three-quarters of a glassful. The intense shock, the seat of the wound, etc., led us to diagnosticate a penetrating wound of the liver, with profuse internal hemorrhage. Besides there was no doubt an intra-abdominal wound of great depth, for at the moment that the stab was given, Professor Gailleton, who was facing the President in his carriage, heard a dull sound as from a very violent blow such as one given with the fist. Hence we concluded that the poignard had been thrust in clear to the hilt. I placed the President in a position so as to facilitate the flow of blood towards the nervous centres and to ward off death as long as possible; a handkerchief was applied to the wound and held there. All this time the horses were being driven at a gallop towards the prefecture where M. Carnot had his apartments, about seven to eight hundred yards distant.

On our arrival there, the President, who was in the same condition and had given no signs of life beyond feeble sighs and two or three unsuccessful attempts at vomiting, was carried to his rooms and placed upon his bed, with his head as low as possible.

While the necessary instruments, dressings and antiseptic solutions were being brought from the Hotel Dieu, napkins filled with ice were applied locally and attempts at rousing him were made by flagellation of the face, calling in a loud voice, etc. A few minutes later a bed was prepared for the operation in the same room, the illustrious patient was lifted onto it and the operation begun, which seemed to be the only means, if not of saving his life of, at least, prolonging it.

Convinced by another examination that a wound of the liver was in question and that the immediate danger was due to internal hemorrhage, I did not hesitate to perform lateral laparotomy, taking the wound as the point of departure. Introducing the left index finger through the original wound I had no difficulty in recognizing the subjacent liver. A clot of dark colored blood escaped after this rapid exploration. At this moment the collapse instead of diminishing appeared to become worse; therefore anæsthesia was out of the question. I immediately enlarged the wound from above downwards, by an incision from ten to twelve centimetres in length and running obliquely along the linea alba. I was struck by the little blood in the abdominal cavity. The subjacent viscera were easily wiped clear of blood, and on stooping down I perceived under the false ribs the left lobe of the liver to present a bleeding aperture on its convex surface. I explored this surface with the end of my index finger and I soon discovered a clean cut wound of eighteen to twenty millimetres length, corresponding well, in form and direction, to that of the skin. The blade of the weapon had penetrated deeply. During these manœuvres of exploration and local compression the hemorrhage ceased. A strip of iodoform wicking was substituted for my finger and introduced with a pair of long handled dressing forceps. A careful examination of the neighboring organs revealed nothing abnormal. The mesentery, the accessible portion of the stomach, the intestine, the gall-bladder, etc., were rapidly examined and found to be uninjured as I had supposed *a priori*, and neither gas, bile nor intestinal contents were observed to escape. The finger could detect nothing on the lower surface of the liver. From the first cut with the knife, under the influence of the pain, the President came out of the deep collapse. He complained of suffering at the site of the wound, and pronounced a few words: "Oh, doctor you hurt me," several times,

in a very intelligible and fairly strong voice. Once he said: "Look, I have typhlitis." At the same time his pulse improved, it then beating 140, although his general condition remained the same, so that we gathered a ray of hope. Up to then I had been assisted by Professors Gailleton, Lèpine, the military physicians Kelsch, Albert, Viry, Demandre, and the doctors Rebatel, Masson, etc. In the meantime Professors Ollier, Monoyer and Doctors Gangolphe, Fabre, etc., had arrived. Their assistance was of particular value.

With Professor Ollier I examined the depths of the incision again. My eminent colleague, whose great authority was so valuable to me then, examined the wound and recognized the hepatic wound, the necessity of hemostatic tamponing, and with common accord I made a second incision towards the median line, of five to six centimetres. The margins of the wound were turned outwards with the hemostatic forceps clinging to them and serving as tractors and another examination made. The piece of wicking which had been withdrawn was found to be soaked in blood. This we did not regard as of any great importance. To be assured we replaced it with another which was packed as tightly as possible into the wound. The surgical indications had been fulfilled.

Was it necessary to do more? Was the liver to be sutured? We did not think so and for various reasons. In the first place the grave state of shock contraindicated any operation of long duration. For in order to get at the wound which was two or three centimetres above the margins of the ribs, a resection would be necessary. The liver though of small volume, it either being normally thus or possibly from the rapid depletion of blood, was natural. After a consultation Professor Ollier and I proceeded to tampon antiseptically and arrest hemorrhage. The hepatic wound, was stuffed with iodoformized wicking; over the external wound, a layer of slightly iodoformized gauze and over this numerous layers of sterilized gauze were placed. For a long time I exercised slight pressure down upon the wound with the palm of my hand. We feared a return of hemorrhage and one of us held the dressing, alternately. Towards half past eleven, on taking off a few of the uppermost layers of gauze, we found the deeper ones infiltrated with blood. Some of these were removed, though in general we thought it rather due to imbibition of blood remaining in the abdominal cavity rather than to a continuation of the hemorrhage. Besides from the moment that the operation was commenced and the hemorrhage checked M. Carnot, as he assured us himself, came out of the profound collapse.

He answered clearly, with perfect lucidity, to questions; from time to time he took a piece of ice or a teaspoonful of iced champagne. Between eleven o'clock and midnight, at intervals of twenty to thirty minutes, two subcutaneous injections of a gram of ether were given. Towards midnight the President appeared to suffer greatly and two injections of the muriate of morphine (one-half centigram) were administered at regular intervals. Yet the patient did not react. His face was motionless, extremely pale and cadaveric; his pulse, which from time to time seemed to improve, became smaller and smaller; his extremities were cold and death apparently was approaching. With a calmness and resignation that were truely heroic he slowly became weaker, without a word of regret, or of blame. At no moment did he allude to the attempt on his life. Several times when attention was called to his sufferings he complained of pains in the epigastric region on a level with the wound, and in his loins.

When he asked for Colonel Chamoin, I informed him that he was there and that all his friends were about him. In a voice that was still strong, he said: "I am very much touched by their presence and I thank you for what you do for me." A few minutes after, and at a half hour after midnight, the signs of dissolution suddenly set in. At no time was there nausea, or vomiting, and though he was two or three times seized with difficulty in breathing, yet he remained calm till the end, which was announced by a few convulsive tremblings especially in the region of the diaphram and of abdominal muscles, so that if the dressing had not been firmly compressed the intestine would have been forced out. At this moment venous hemorrhage issued in a large quantity, confirming our opinion of internal hemorrhage. For immediately after the deed and during the long drive to the Prefecture in his

half-seated position, the blood had collected in the pelvic cavity and the iliac fossæ.

The necropsy was done at the suggestion of Professors Gailleton and Ollier. The family physician of the President, Dr. Planchon, who had arrived with Madame Carnot, was also present. The following is the record:

"The undersigned doctors of medicine have proceded to-day to the necropsy of the President of the French Republic. The following lesions were discovered:

1. The wound was situated immediately beneath the false ribs of the right side, three centimetres from the xyphoid appendix; it measured twenty to twenty-five millimetres, and the blade in penetrating completely severed the corresponding costal cartilage.

2. The blade of the weapon had penetrated into the left lobe of the liver from five to six millimetres and near the suspensory ligament. It perforated the organ from left to right and from above downwards, wounding in its passage the portal vein which it opened at two places.

3. The path of the weapon in the interior of the liver was from eleven to twelve centimetres. A mortal intra-peritoneal hemorrhage was the result of this double perforation of the portal vein.

Signed:

DRS. LACASSAGNE, HENRI COUTAGNE,
PONCET, OLLIER,
LEPINE, REBATEL,
MICHEL GANGOLPHE, FABRE.

LYONS, June 25, 1894.

The injury to the portal vein, in that laparotomy could not be done immediately after the attempt on the President's life, was necessarily fatal. But we were convinced that if he had survived this for three hours it was due to our intervention alone. Without, indeed, being able to diagnosticate the lesions of the portal vein, it is beyond doubt that the firm pressure over the wound sufficed to arrest the hemorrhage, for very slight compression will cause venous hemorrhage to cease. The reaction from the collapse was due to this.

TRANSLATIONS.

APPENDICITIS AND PERI-APPENDICITIS.

Cuffer (*Le Bulletin Medical*, June 24, 1894,) draws a distinction between typhlitis properly so-called (that is to say typhlitis of the cecum) and typhlitis of appendix. He says that in order for the fecal matter to harden and accumulate in the cecum there must exist primarily an extreme intestinal atony, a paresis of the muscular walls of the intestines. This may be brought about by an old inflammation such as dysentery, or an irritation of the neighboring peritoneum; in every case Stokes's law will explain the relative importance of the subjacent muscles. Certain exercises predispose to typhlitis, such as the game of croquet, which when played in a certain manner occasions repeated blows upon the region of the right flank; in the same order he has observed atony of the cecum and a stercoral typhlitis in a professional billiard-player. The bicyclist also is, through the exercise indulged in, rendered subject to the development of intestinal atony with predisposition to typhlitis.

The atony of the cecum once produced, no matter in what manner, there results a progressive accumulation of fecal matter; this gives rise to a vague pain in the right iliac fossa, a sense of ill-defined heaviness; the patient has an instinctive tendency to rest his hands upon this painful region. This constitutes the first period of typhlitis, the period of stercoral tumor; there may be found in the iliac fossa an elongated mass having the direction and the form of the cecum, non-painful, and giving on palpation the sensation of a depressible lump of clay. Under the use of laxatives this tumor will disappear, but the initial cause persists. Appropriate treatment must be instituted to prevent a new stagnation of the fecal material.

If no intervention is made, at a variable period a new phase appears; to the uneasiness succeeds a veritable pain, a pain

increased by motion, jolts, and exacerbated by palpation. In the place of the cecum may be found a thick mass, resisting and painful; this is the inflamed cecal wall; a fever exists, the belly is tympanitic, the tongue is coated, appetite nil, there are eructations, nausea, vomiting, all the phenomena clearly indicate an obstruction to the feces. At times in the beginning of this period there may be observed a diarrhœa—the diarrhœa of constipation; below the obstruction there is a congestion of the intestine with a glandular hyper-secretion. It is important now to administer a laxative or an electric bath; there follows a sudden and profuse escape of fecal material.

The painful phenomena demand attention. During the inflammatory period of typhlitis there exist paroxysmal exacerbations of pain. There are colics which approach in their characteristics the hepatic or nephritic colics. There is on the part of the nervous system an intense reaction in proportion to the extent and importance of the causal lesion; the meteorism, the intensity of the pains and their distant extension, the drawn face, the tendency to syncope, the feeble pulse, all seem to indicate a peritonitis, but there is no fever, and with rare exceptions no vomiting.

In appendicular colic the point of maximum intensity of the pain is found at MacBurney's point, and the pains are localized in the iliac fossa without any marked tendency to radiate to other portions of the belly. On the contrary in typhlitis accompanied by peritonismus (Gubler's name for irritative spasm of the peritoneum), the pain is more extended, more diffuse, more abdominal. Moreover one may feel the fecal tumor.

There are two main varieties of appendicitis. The first variety comprises those cases due to primary inflammation of the organ, from ulcerations due to various causes forming in the vermiform appendix and causing the appearance of a typhlitis of the appendix. In the second group are classed the forms which are due to the lodgment of a foreign body in the appendix and which evolve, so to speak, in two stages—a primary phase more or less latent corresponding to the stagnation of the foreign body in the appendix; then a second stage characterized to the inflammation of the organ. The foreign body may be very diverse; biliary calculi, apple seeds, kernels, fecal masses, scybala.

Symptomatology of appendicitis. Just as in the beginning of stercoral typhlitis there is a special morbid state characterized by the constipation with the formation of a fecal sausage, associated with appendicular colic. It it almost impossible to absolutely distingnish between cecal peritonismus and appendicular colic. This is the main phenomena of beginning appendicitis, viz., appendicular colic, single or repeated, intense or slight, occurring in paroxysms or alternating in general with a dull pain fixed at the level of the appendix. Fever does not exist; it is the pain with these special characteristics joined with absence of constipation which decides the diagnosis. —D.

Headache.

The following prescription embodies all of the therapeutic virtues claimed for the numerous proprietary "anti's" (with varying affixes) of unknown composition, with which the medical profession is being overwhelmed in recent times:

℞
Caffeinae citratis	gr. x
Acetanilidi	gr. xxx
Sodii bromidi	ʒ i
Sodii bicarbonatis	ʒ ii

Misce et div. in chart x. Sig:—One powder, repeated if necessary, at intervals of one hour.

Infantile Convulsions.

Dr. Jule Simon, in *El Siglo-Medico*, prescribes this combination:

℞
Chloralis	
Potassii bromidi	āā gr. xv
Codeinae	gr. ss
Tinct. moschi	
Tinct. aconitis radicis	āā M vi
Syrupi aurantii flori, q. s. ad	ʒ iii

M. ft. solut. Sig.—Dose: One teaspoonful, by mouth, or in enema if it cannot be swallowed.

Painful Pharyngitis.

Eng. Med. Press gives the following formula:

℞
Morphinae sulphatis	gr. iv
Acidi carbolici	ʒ ss
Acidi tannici	ʒ ss
Glycerini	ʒ iv
Aquae	ʒ iv

M. ft. solut. Sig.—Paint the throat two or three times daily.

For Psoriasis.

℞
Ichthyol	
Acid. salicylic	
Acid. pyrogallic	
Aristol	āā gms 2½
Vaselin	
Adipis	
Lonolin	āā gms. 30

M.
A powerful ointment, to be used in small quantities.

THERAPEUTICAL SUGGESTIONS FROM FOREIGN JOURNALS.*

HECTIC FEVER IN PHTHISIS.

Dr. A. von Szekely (*La Semaine Medicale*, No. 38, 1894,) advises the following mixture in the hectic fever of phthisical patients:

℞	Ergot.....		
	Salicylate Soda.....āā	10	o (℥ijss).
	Water.....	180	o (℥v ℥v).

Infuse the ergot in the water and then add the salicylate of soda. Four tablespoonsful per diem.

If one will produce produce a complete cessation of the fever for the whole night then let the patient take five tablespoonsful in the course of two hours during the evening. The ergot is added to prevent the roaring in the ears which accompanies the salicylate when given in large doses. (These two drugs are mutual antidotes according to a recent German writer). *Trans.* Of all the measures employed in hectic fever salicylic acid and particularly the soda salt which is better tolerated by the stomach are the most active remedies. A portion of the salicylic is elimated by the lungs as salicylic acid thus disinfecting in a certain measure, the decomposing products to which absorption the hectic fever is due.

SALICYLIC ACID LOCALLY IN RHEUMATISM.

Dr. Thomas Manley (*L'Union Medicale*, No. 71, 1894,) praises salicylic acid in acute articular rheumatism where it is claimed to exert a marvelous action when applied locally. In articular pains whether the joints be swollen or not, in lumbago, sciatica, intercostal neuralgia, as well as in gonorrhœal rheumatism it acts well. He employs the following formula:

℞	Chloroform.....	20	o (℥v).
	Tr. Opium.....		
	Salicylic Acid.....āā	16	o (℥iv).
	Alcohol.....	120	o (℥iv).
	Sweet Oil.....	360	o (℥xj).

To be applied locally.

TREATMENT OF CHOREA.

Prof. Dujardin-Beaumetz (*Revista de Ciencias Medicas de Barcelona*, No. 11, 1894,) before attempting to treat a case of this disease would differentiate the variety, for there first must beeliminated the chronic forms, double athetosis, cerebellar hereditary ataxia; these choreic affections are completely incurable. Ordinary chorea, Sydenham's variety, is divided in two great groups: 1. Chorea of rheumatic origin and chorea associated with hysteria; this latter variety is by no means rare in childhood. Cases in which these two factors are mixed give rise to therapeutic doubts. In the rheumatic variety it is wrong to reckon upon an effect from the salicylate of soda; antipyrine in four doses per diem of a gram in each will be much more efficacious. Legroux thinks that this remedy is inferior to the bromide of potash in the hysteric variety. Though phenecetine has not given constant results, exalgine on the contrary has yielded a number of rapid cures even in eight days. A moderate daily dose is 0. 40–0.75 in doses of 0.10. Dujardin-Beaumetz is of the opinion with Bardet and Moncorvo that a daily dose of 0.30 is quite large enough: antipyrine should be reserved for rheumatic cases. In chorea gravis he advises chloral (1.0–4.0). The hysteric variety is recognized by the stigmata of this affection, anæsthesia of the palate, other disturbances of sensation, hysterogenic zones, and a history of inherited nervous diseases. The bromide in a daily dose of 4.0–5.0 and arsenic are absolutely indicated; hydropathic measures are also valuable as they combat the depression produced by the bromide massage and gymnastics.

TREATMENT OF VULVAR PRURITUS.

In the (*Journal de Medicine de Paris*, No. 25, 1894,) the following treatment is advised:

1. Pruritus of diabetic origin. Examine the urine, if sugar be present regulate the diet, administer specific treatment and apply very hot water locally.

2. Pruritus dependent upon a chronic eczema of the genital organs a gonorrhœal vaginitis, simple leucorrhœa or vaginismus with reflex hysteric manifestations.

Allow no stimulating foods nor drinks. In profuse leucorrhœa either recent or chronic, inject morning and evening a warm two-quarts solution of permanganate

* In charge of the Translator, F. H. Pritchard, A.M., M. D.

of potash, 1:1000, into the vagina. Apply locally three times a day the following:

℞

Water	450	0 (℥xiv).
Alcohol 90 per cent	50	0 (℥ss).
Bichloride Mercury	1	0 (grs. xv).
Indigo Carmine		05 (gr. j).

When the burning and itching are severe, which is especially in the second half of the night, apply water as hot as can be borne. Avoid all salves with a fatty base as they are liable to ferment and to increase the irritation.

HEMICRANIA.

In the *Gazzetta Degli Ospedali*, No. 75, 1894, the following pill is recommended in migraine:

℞

Sulphate Quinine	3	0 (grs. xlv).
Powdered Digitalis Leaves.	1	50 (grs. xv).
Syrup q. s.		

Sufficient for thirty pills. Two to six during the attack.

TREATMENT OF EPITHELIOMA OF THE SKIN.

Dr. Gavino (*Journal de Medicine de Paris*, No. 25, 1894,) claimed to have cured all the cutaneous epitheliomas coming under his observation without exception, by application of the following paste:

℞

Fuming Nitric Acid	10	0 (℥ijss).
Bichloride Mercury	4	0 (℥j).
Berzelius' Paper. q. s. to form a paste		

Apply locally once every twelve days.

The most extensive epithelial cancers will yield in a short time to this topic application and cicatrization will follow rapidly and under good conditions.

RENAL ALTERATIONS IN SULFONAL POISONING.

Dr. R. Stern (*Hospitals-Tidende*, No. 13. 1894,) communicates a fatal case of sulfonal poisoning in a seventy year old woman who, suffering from a mental disease, had received about 175 grams of sulfonal in daily doses of a gram, at first and later of two grams. Though the drug was occasionally discontinued, eight days before death hematoporphynuria was observed and she died after having laid comatose for two days. The kidneys presented an extensive necrosis of the epithelium of the canaliculi especially in the tubuli contorti. In portions of the cortical section there were places where the epithelium could not be colored at all. The glomeruli were not distinctly affected, the capsules were somewhat thickened and contained here and there slight hemorrhages which were also found scattered through the renal tissues. Some increase of the interstitial tissue and thickening of the arterial walls. The latter he thinks are but senile changes while the extensive necrosis of the epithelium is due to the sulfonal alone. As soon as hematoporpharine or casts are observed in the urine the drug must be immediately discontinued.

AUXILIARY TREATMENT OF SYPHILIS.

Dr. Charles Stern (*Gazette des Hopitaux*, No. 74, 1894,) claims that though antisyphilitic treatment in persons in former good health will usually suffice it is by no means all that is to be done in managing this disease. There is besides an auxiliary treatment which must be considered. It properly consists of other remedies than specifics, hygiene and bathing. As to the combination of other remedies with antisyphilitic treatment there are many prevously existing states which affect and are affected by the ingrafted syphilis. Anema is one of the most important; it is rarely due to syphilis alone but existed anteriorly, at least in the male. In the female it is more frequent though if occuring after growth has ended and the organism has entered into a state of nutritive equilibrium it is less frequent. A sort of cachexia may result which inclination was present before and which the syphillis only unmasked. Though mercury has been claimed to increase the anemia Mauriac does not believe it. He regards it as a valuable reconstructive, and only to be discontinued when it is not tolerated or seems to have exhausted its strength. In the associated chloro-anemia, anemia and neurasthenia reconstituents must be employed. The iron preparations and tonics are not only compatible with mercury and iodine but they even favor their action.

EARLY TREATMENT OF SYPHILIS.

Dr. Jullien (*Muenchener Med. Wochenschrift*, No. 25, 1894,) believes in the abortive treatment of syphilis and that as soon as a chancre is diagnosed. He employs subcutaneous injections of calomel-1.0 calomel; 10.0, vasseline. A moderate

dose is injected every fourteen days deeply into the buttocks four to five cms. outside of the sacrum, under rigid antiseptic precautions. This prevents the development of the chancre and a later and much milder outbreak of secondary symptoms, after two to four months.

If one begin two or three weeks after appearance of the initial lesion this fortunate modification will not be observed. As to later symptoms he has after four years observation not seen them appear. Treatment must be continued for five to six months and the injection varied according to the individual; later one every twenty to twenty-five days will suffice. He believes it poor advice to await the development of the secondary symptoms and begin treatment when the whole organism has become infiltrated. A little cocaine added to the solution will prevent the pain of injection. He is a warm advocate to abortive treatment.

CHLORINE WATER IN DIPHTHERIA.

Dr. Schubert (*Wiener Med. Presse*, No. 24, 1894,) speaks highly of chlorine water as a specific in diphtheria. He has employed it in several severe cases of the epidemic variety, with brilliant results. The effect is seen at once, for progress of the disease is stopped, the fever drops, the general condition improves, the appetite becomes better, the throat clears up, and the membranes gradually disappear. This action is so characteristic that it is always observed. He prescribes the following:

℞ Chlorine Water..... 40 | o (5j¼).
Distilled Water..... 20 | o (3v).

In grave cases every hour, and in those less severe every two to three hours, a teaspoonful of this solution is administered; lengthen the intervals or decrease the dose with improvement. The other children and members of the family should take a teaspoonful two to three times a day as a prophylactic. Thus administered he has never observed an extension of the disease in families where it had broken out. As chlorine is the strongest bactericide its action is easily explained. He has never observed any disagreable consequences of this treatment so that the fear of using this remedy is wholly groundless; it is feared because it is not understood. On ccount of the acrid and biting odor it is best to hold the noses of small chiidren in giving it. The taste is not disagreable but somewhat sour.

LIVER AFFECTIONS AND EPISTAXIS.

Prof. Verneuil (*Muenchener Med. Wochenschrift*, No. 25, 1894,) believes that most all cases of epistaxis are due to a liver affection and if observed in children without distinct hepatic derangement then the disease is latent. He warns against stuffing anemic children having frequent nose-bleed with toxic drugs when these only increase the congestion and do no good. He has cured many cases by alkalies, vegetable diet and douches to the region of the liver.

FLECHSIG METHOD OF TREATING EPILEPSY.

Dr. L. Stembo (*St. Petersburger Med. Wochenschrift*, No. 15, 1894,) has tried in nine cases the Flechsig method of treating epilepsy which consists in prescribing first exclusively opium and then to follow this with the bromide, and with encouraging results. In all his cases the attacks ceased after a treatment of several weeks, the attacks either disappearing altogether or becoming very infrequent. He gives smaller doses of extract of opium than Flechsig, (0.02–0 06) several times a day for a month and increases the dose up to 0.24–0.36. Then he suspends the drug and prescribes the bromide 3.75–7.50 *per diem*, for four weeks. This dose is gradually diminished to 1.5 a day.

Urticaria of Children.

We find in *L' Union eMdicale* this prescription:

℞ Chloralis..... 5 i
Pulv. camphorae..... 5 i
Pulv. acaciae..... 5 i
Cereti simplicis..... 5 i

Mix and triturate well. Sig.—Apply locally to affected parts.

Acute Coryza.

℞ Morphinae sulph..... gr. i
Cocainae hydrochloratis..... gr. iii
Menthol..... gr. vi
Pulv. acidi borici..... 5 ii
Bismuthi subnitratis..... 5 iii
Pulv. benzoini..... 5 iii

M. Sig. — Snuff a pinch up nostrils several times daily.

EDITORIAL.

DO NOT TURN OUT THAT CLOT.

For more than a century at least, obstetricians have been practically unanimous in making one of the essentials in the treatment of post-partum hemorrhage, emptying the uterus of clots of blood. Turn out that clot, has been the constant and common chorus of obstetric teachers. Yet it sometimes happens that rules in medicine have exceptions; these rules are not always like Median and Persian laws in their unchangeable character. Though to some it may seem obstetric heresy it can be justly asserted that there are cases, very rare it is true, in which the injunction to turn out that clot, should be changed into, Do not turn out that clot. Two cases will be given in illustration of the advice here suggested:

The first is quoted from Contamin's* monograph, published in 1877: "There are nevertheless cases in which clots seem to oppose a barrier to the flow of blood. In one of his patients Professor Bouchacourt three times emptied the uterus of clots contained in it. Every time the effusion recurred, and clots were reformed in the uterine cavity. The patient was exhausted and syncope was imminent. As the size of the uterus was not very great and did not seem to increase, this condition indicating that the hemorrhage was suspended, the clots were left in the uterus." "The hemorrhage did not recur and the following day the clots were spontaneously expelled."

"In this case the clots had the role of an obstacle to the flow of blood, and one might ask what would have happened if the obstetrician had determined at all hazards to empty the uterus. Only in exceptional cases can this example be followed. Nevertheless we are authorized to temporize when the hemorrhage seems arrested, and especially when the consistence of the uterus indicates the return of its contractions."

The second case is found in the Transactions of the Indiana State Medical So-

*Etude sur les hemorrhagies qui surviennent pendant les suites de couches.

ciety for 1884, and is from that veteran, so honored whereever known, Dr. James F. Hibberd. Dr. H's patient was 28 years old, and the history is of her second confinement. "Her labor was rapid, and relatively easy, the second stage continuing about two hours. My hand upon the abdomen witnessed that the womb was fairly contracted immediately after the extrusion of the child, and then the ordinary time was consumed in attention to the child, say fifteen minutes. Turning to the mother I found that she was bleeding freely, which was not arrested by subjecting the womb to massage through the abdominal walls, nor was the placenta thereby passed down into the vagina. Promptly following up the chord the uterus was found in a state of hour-glass contraction, the constriction being about the middle, with the placenta in the upper division. With prudent haste I dilated the stricture with my fingers bunched pyramidally, to find the placenta not lying loose into its abnormal chamber, but more firmly adherent than I remember to have met with before, not peeling off from its attachment, as adherent placentas usually do, but requiring to be crushed off, as it were, by careful rigor with the ends of my fingers. This task performed, by external manipulation I secured contraction of the womb as I withdrew my hand, and immediately gave her a full dose of fluid extract of ergot, a medium dose of morphia and a moderate dose of alcohol, then sat down by the bedside with my left hand on the abdomen over the uterus, which was now slightly enlarged, my right hand fingers on the pulse, and awaited events. They came rapidly. In removing the placenta the patient's head had been placed on the same horizontal plane with her body, and it was left thus. Her pulse was quick and feeble. She was anxious and distressed, complained of flashes of heat and a sense of suffocation, the pulse failed rapidly, was no longer discernable, the breathing ceased, and all was quiet as the grave—my patient had fainted, and still I moved not, nor allowed any one else to move. No water to her face, no camphor to her nose, no rubbing 'of the extremities of my patient lying there in the similitude of death; but I sat and watched and hoped. Presently there was a faint wave at the wrist, then a half developed sigh, and anon the fullness of respiration in my patient and a restored circulation were the evidences of her return to conscious life, and still I sat and watched. In a few minutes the breathing was again hurried, another expressed apprehension of smothering, and again the pulse faded to indistinctness, and for the second time my patient had swooned from loss of blood, and yet another time no restoratives were applied, but the case left to the recuperative resources of nature, and they were equal to my anticipations and desires. The phenomea of active life soon re-appeared and reached a satisfactory state, etc." "No subsequent evil was manifest, and the patient had speedy and complete recovery."

From the comments made by Dr. Hibberd upon the treatment, the following are taken: "I deem it a fair scientific conclusion that where a syncope is due to a hidden loss of blood, or other acute impression in a system otherwise in a physiological condition, there will be an automatic restoration, unless the shock itself is fatal, and in such case the scene is closed at once, with, of course, no margin for help." "In my puerpera I looked for syncope, and desired it for remedial purposes." "The second swoon was not anticipated, but did not carry with it any apprehension of increasing evil, as it was not regarded as an evidence of continued hemorrhage because of the testimony of the hand still held in the inquiring position on the abdomen over the uterus." "If in this case I had become alarmed at the enlargement of the womb after the ex-

hibition of the drugs, and by massage or the insertion of the hand had removed the clot from the uterus and attempted to maintain a better contraction of the uterus by manual efforts or the intra-uterine use of ice or hot water, or a styptic, I am of the opinion I should have sacrificed my patient; and I am further convinced that if, misapprehending the significance of the syncope, I had called aid and instituted active measures of restoration, I should have done an uncalled for and unwise act, bringing my patient's interest into further jeopardy."

We have quoted quite fully from Dr. Hib berd's paper, not only for the enforcement of the truth that it is not always good practice to "turn out that clot," but for the graphic description of post-partum hemorrhage, as well as to illustrate the necessary calmness of the obstetrician in this great and immediate peril.

Whatever criticisms of the particular steps in the treatment may be made, whatever other obstetricians might have changed, or added, the result testifies very clearly.

And are we wrong in adding, wisdom is justified of her children?

But let it be borne in mind, that it is only in exceptional cases the obstetrician is right in departing from theestablished rule.

AN ERROR CORRECTED.

Some un fortunate and unexplained accident credits the article on "Placenta Previa Centralis" which appeared in the REPORTER for July 21, 1894, to the pen of J. Campbell Edin, M. D., C. M. (McGill), L. R. C. P., whereas the writer's name should have appeared, J. Campbell, M. D.,C. M. (McGill), L. R. C. P. (Edin).

ABSTRACTS.

THE PHYSICAL DIAGNOSIS OF GALL STONES.

Gebhardt observers that the attack usually begins four or five hours after the chief meal—that is, shortly after the entrance of the stomach contents into the duodenum. According to the size and position of the stone after it has passed into the common bile duct, distention of the gall-bladder may be recognized at once, or later (when the gall-bladder has been copiously filled, or not at all). The swelling lies between the right parasternal line and the anterior axillary line, mostly a little to one side of the right rectus muscle. If the gall-bladder is much distended it may give rise to errors in diagnosis. This distention only takes place in a minority of the cases. It may be absent owing to the smallness of the gall-bladder, or to the obstruction being incomplete, or lasting too short a time. It occurs in severe attacks, or in those who have had repeated attacks. The commencement of the attack may last a couple of hours without pain, during which time the ball-bladder may be palpable. The shrinking of the swelling shows the end of the attack. After a severe attack a friction sound, synchronous with inspiration and expiration, and sometimes of diagnostic value, may be heard over the gall-bladder. This is due to local peritonitis, and it explains the continuance of pain. An ice-bag is more useful here than warm applications. The liver may swell after severe attacks and fever be present. Attacks may occur with pain and fever, but there is neither swelling of the gall-bladder nor of the liver, and no stone is found in the stools. It is thought that the stone slips back into the gall-bladder, but other possibilities exist. The swelling of the gall-bladder may be due to obstructions having other causes; it does not occur in cardialgia. When, after several attacks no stone is found, no friction sound heard, and no swelling of the gall-bladder felt, cholelithiasis may, with tolerable certainty, be excluded, and neurotic hepatic colic may be assumed with great probability.—*British Medical Journal.*

TWO CASES OF GENERAL SUPPURATIVE PERITONITIS FOLLOWING THE RUPTURE OF A PYOSALPINX DURING LABOR; DEATH; AUTOPSIES.

BY RICHARD BARTLETT OLESON, M. D.

The writer was unable to discover any anatomical reason for the comparatively good health of the patients during the first twenty four-hours. In each case there was no obstacle to the free outflowing of the pus, and it would seem as though symptoms should have resulted at once, upon the end of labor.

CONCLUSIONS.

1. Particular attention should be paid by the obstetrician to a history of slight obscure febrile attacks during gestation, especially when there is any discoverable cause for a possible pelvic lesion. These attacks are generally referred to as "malarial" by the patient, but in a nonpaludal region, if quinine does not vanquish them, and an examination of the blood reveals nothing, the pelvic viscera may be looked to with decided profit.

2. In addition to the usual examination as to the condition of the urine, position of fetus, size of pelvic straits, etc., there should be in every case an attempt to discover the condition of the uterine adnexa, with an especial view to the possible existence of purulent collections, the limiting adhesions of which are partiularly liable to yield to the terrific strain upon the whole pelvic contents in childbirth. In the class of cases usually seen by the members of this society this will be found somewhat difficult, but where one is able to examine a woman before the ninth month of gestation the procedure should be fairly easy, and easy in direct proportion to the earliness of time at which the accoucheur is retained.

3. It should be regarded as an obstetrical axiom that no woman with a pyosalpinx should ever be allowed to enter labor carrying this pus in her body. Undoubtedly many a woman has gone through labor safely in spite of the existence of this condition, but it never can be considered as anything short of an accident which ought not to again occur. The powder magazine was there, the match was applied but for some reason the powder did not burn. If all statistics could be known undoubtedly even such a *dernier resort* as Cæsarian section, would be found to offer better results both as to mother and fetus, then the persistence of the pyosalpinx unmolested, especially an aseptic Cæsarian section performed as an operation of convenience and election.

4. If a woman with a pyosalpinx has once entered upon labor there is then no precaution, short of a laparotomy, which may be taken by the obstetrician, that can avail him anything in the pervention of general peritonitic infection. No detail of strict asepsis should be neglected, yet in spite of all endeavors tearing of the slight adhesions about the tube may occur, with most lamentable consequences.

5. It is especially noteworthy that in both of these cases labor was very rapid of completion and the pains strong and expulsive. Evidently this fact has direct bearing upon the causation of the rupture of adhesions.

6. Contrary to the general idea, the fact that over twenty-four hours have elapsed since the delivery of the placenta with no bad symptoms whatever, does not militate against the diagnosis of general suppurative peritonitis, due to a ruptured pyosalpinx, and the sudden rise of temperature occur for which no other local nor general causes may be found.

7. The early diagnosis of this affection is especially difficult, because:

a. The abdominal parieties are very much relaxed, thus requiring considerable gaseous distention to exist before tympanites is noticeable or the liver dullness interfered with.

b. The prevalence of after pains is so universal that the first subjective symptom, the danger signal, may be entirely overlooked, being attributed to a cause entirely separated from the true one.

c. In at least a certain proportion of cases collapse, vomiting and abdominal pains may be entirely wanting, and symptoms be referred to another part of the body.

8. Once developed, any intrauterine measures looking to the relief of this disease are worse than useless, only serving as a means of wasting priceless moments. There is but one treatment affording the least chance of help, immediate laparotomy under strict asepsis with drainage, aided by free saline catharsis.

CURRENT LITERATURE REVIEWED.

IN CHARGE OF ELLISTON J. MORRIS, M. D., AND SAMUEL M. WILSON, M. D.

THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES.

for July. Dr. W. T. Lusk contributes a paper on the

Relative Values of the Various Surgical Methods of Treating Uterine Fibroids.

The author asks the question whether, if the uterine growth is of small size and the pain and vesical discomfort are slight, it is not good practice to delay a little, and control, if need be, an attendant menorrhagia by the curette, by the tampon, or ergotine, or the methods of Apostoli. He declares that the argument in favor of more radical measures, because of the supposed liability of myomata to malignant changes, especially in patients nearing the climacteric, has clinically little weight. Of the palliative measures, he says that curetting unquestionably furnishes the greatest number of disappointments. He reports a case in which a daily combined uterine and vaginal tampon of iodoform gauze caused a diminution of one half in the size of the tumor. Of vaginal enucleation he says, "The operation is, of course, applicable to tumors of small sizes. It would be contra-indicated in multiple and subserous fibroids, by inflammatory conditions, and in fixation of the uterus by old adhesions. Great care needs therefore, to be taken in the prefatory diagnosis. Not only should careful bimanual examination, (best under ether) be employed, but the cervix should be sufficiently dilated to permit the most thorough digital exploration of the uterine cavity. Nor is it to be forgotten that the good results which have restored the method to favor are due to aseptic methods. During the operation nearly continuous irrigation of the uterine cavity should be employed, and at its completion the emptied sac should be carefully packed with iodoform gauze." When radical measures are deemed necessary, the author thinks that, where practicable, vaginal hysterectomy should take precedence of the abdominal form. When the tumor much exceeds the size of a child's head, it is as a rule advantageous to attack it from above. The question of castration is a legimate one although it has been decried of late. The author quotes the expressions of others on the subject and seems to be of the opinion that in certain cases it may be the best procedure. It is not to be performed in large tumors or cystic growths or where adhesions prevent the complete removal of the ovaries. Under favorable conditions, complete extirpation of the uterus is the wisest course; but excessive anæmia, a feeble circulation, or the length of time needed to separate adherent viscera should be taken into consideration. All pedicled growths should be tied off and the uterus allowed to remain. The author is of the opinion that complete extirpation of the uterus is a more severe and mutilating operation than the supra-vaginal amputation.

Dr. Frederick P. Henry gives the

Clinical Report of Two Cases of Raynaud's Disease.

The author thinks that many cases of symmetrical gangrene reported as examples of Raynaud's disease have an anatomical basis in endarteritis obliterans, but they are in his opinion spurious. There is little to support the theory that peripheral neuritis is the cause of Raynaud's disease, and the author thinks that the theory of arterial spasm is most in accord with the clinical phenomena. In those cases in which hæmoglobinuria is observed the author thinks this symptom dependent on an excretion of hæmoglobin which has been separated from the red corpuscles in the peripheral asphyxiated parts.

The paper is illustrated with colored cuts of the condition as presented by one of the cases reported.

Dr. Thomas G. Manley contributes an article on

Gonorrhœal Arthritis,

reporting several cases. He divides the cases into the sub-acute, or abortive and the acute severe gonorrhœal arthritis. The one symptom more valuable than all others in these cases is the persistence of pain and inflammation in one articulation. Another is the chronicity of the effusion into the joints. In the treatment he states that effective remedial measures are efficient in practically all cases of gonorrhœal arthritis, if the cases are seen before organic changes have taken place in the joints. For internal medication mercury occupies the first place. First as a purgative and hepatic stimulent, and secondly in small, but oft repeated doses as an antiphlogistic. It may be administered by inunction, fumigation, hypodermatically or by the mouth. It should be given with a free hand until there are signs of amelioration or its toxic action is becoming manifest, when it should be discontinued. Pain will require the use of anodynes. If there is a malarial, rheumatic, or strumous complication, quinine, colchicum, and the alkalies, or cod liver oil should be freely given. The body should be at complete rest; in a comfortable position. Of local treatment the author places the local abstraction of blood as the most effective of all local measures in the early acute stages. The author does not approve of the use of any orthopædic apparatus in the early stages of the disease. But when the intensity of the malady passes over, as the joint is temporarily crippled, a comfortably adjusted bandage

serves a most valuable purpose. Protracted immobilization in plaster-of-Paris is of little use unless the joint is hoplessly destroyed, when the support which it contributes fixes the articular surfaces until ankylosis is complete. Hot or cold applications, emollient poultices, rubefacient plasters, and even the actual cautery, each and all have their place. Surgical intervention is occasionally demanded in grave cases of the disease. Injections of antiseptic substances in the joint have never been successful into the author's hands. When aspiration shows the presence of pus in the joint and constitutional disturbances are marked, then an incision into the joint, with free irrigation should be tried. When the articulating surfaces have been honeycombed by erosions and penetrating ulcers the joint must be sacrificed. The author is of the opinion that, as the system in these desperate cases is in a depraved state and the recuperative powers are very feeble, the only means which holds out any hope of saving life is amputation.

As the result of his experience the author comes to the following conclusions:

First, with reference to diagnosis. This is not difficult to decide when the differential characters of rheumatism and of tuberculosis are remembered. In all of his cases except one there was undisputed evidence of gonorrhœa, though the specific microbe was not found in all.

In none of his cases did perfect functional restoration follow the disease. Hence, urethral arthritis must be regarded as one of those diseases in which complete resorption of inflammatory deposits rarely if ever occurs.

The author's observations lead him to ignore the general view that it is a masculine disease, as there were in his cases, an equal proportion in each sex.

The treatment must be energetic and antiphlogistic. Mercury, if given early, exercises a most salutary influence in the course of the malady. If rheumatism is suspected as a complicating factor, then colchicum with the alkalies is useful.

The local management of the affected part is important. In the early stage free abstraction of blood; later, blisters, lotions, the bandages, etc. After the acute stages have passed, then moderate motion should be instituted if we would avoid or limit the ankylosis.

Myomectomy as a Substitute for Hysterectomy.

is discussed by Dr. E. C. Dudley. Myomectomy he says, should be supplemented by removal of the appendages in the three following classes of cases:

1. Cases in which the appendages are the seat of such disease as would demand their removal under other conditions.

2. Cases in which the enucleation of the tumor or tumors has so injured the uterus as to render it incapable of performing its functions, especially if the injury be such as would cause cicatricial atresia at the uterine ends of the Fallopian tubes. This might be the occasion for the removal of the appendages on one side only. With increased experience this class ought to diminish.

3. Cases in which the uterus contains an additional myoma so inaccessible as to make enucleation extremely hazardous.

The Treatment of Inoperable Malignant Tumors with the Toxines of Erysipelas and the Bacillus Prodigiosus

is the title of a paper by Dr. William B. Coley. In the paper he reports a number of cases, and as the result of his experience presents the following conclusions:

1. The curative action of erysipelas upon malignant tumors is an established fact.

2. Its action is much more powerful in sarcoma than in carcinoma.

3. This action is chiefly due to the toxines of the erysipelas streptococcus, which may be isolated and used with safety.

4. This action is greatly increased by the addition of the toxines of bacillus prodigiosus.

5. The toxines to be of value should come from virulent cultures and should be freshly prepared.

6. The results obtained from the use of toxines without danger are so nearly quite equal to those obtained from an attack of erysipelas, that inoculation should rarely be resorted to.

Appended to the paper is a tabular statement of the cases inoculated by the author.

The remaining paper in this issue is "On the Value of Ophthalmoscopic Corneal Images" by Dr. Ernest E. Madox.

For Painful Defecation

Attending inflammatory pelvic conditions, Dr. Murray (*Norsk Magazin for Lægevid*) recommends the following:

℞

Bismuth subnitrate	gr. ijss
Mercurial ointment	gr. iss
Extract of belladonna	gr. iv-v
Cacao butter, q. s., for one suppository	

Sig —Two suppositories a day. The bismuth is added to prevent irritation of the mucous membrane of the rectum.

In the German army the following application is employed for the rapid cure of *blisters* of the feet incident to long marches.—*Therapeutic Gazette.*

℞

Saponis nigri	p. 52
Aquae	p. 27
Vaselin	p. 15
Zinci oxidi	p. 6
Essentiae lavandulae, q. s.	

M.

Useful in Bronchitic Asthma.

℞

Potassii iodidi	3ij
Ammon carb	5j
Tinct. lobeliae	f3ij
Sp. chloroformi	f3iv
Vin ipecac	f3j
Infus senegae, q. s. ad	f3vj

M.

A tablespoonful in a wineglassful of water every four hours.—*Med. Press and Circular.*

Application for Chronic Pharyngitis.

℞

Iodi	gr. vj.
Potassii iodidi	gr. xij
Mentholis	3j
Glycerini, q. s. ad	3j

M.

Apply with a camel's-hair brush twice or thrice daily.

PERISCOPE.

IN CHARGE OF WM. E. PARKE, A.M., M. D.

MEDICINE.

What We May See in the Sputum.

Microscopical examinations have so far superceded the older methods that we frequently overlook many valuable points of diagnosis that might be observed with the unaided eye. We may first observe the quanity, reaction and consistence.

Patients with bronchitis or cavities, and especially cases of bronchiectasis, have the largest quantity.

Unless contaminated with vomited matter, sputum is always alkaline.

Mucus sputum usually occurs early in acute bronchitis.

Muco-purulent sputum in chronic bronchitis and in phthisis, or in later stages of acute bronchitis and pneumonia.

Purulent sputum (nearly pure pus) indicates a cavity or an empyema.

Serous sputum is fluid, and contains albumen, and is frothy. Characteristic of edema of lungs.

Blood expectorated from the lungs is usually bright red, frothy and alkaline. From the stomach it is dark, nearly brown, and acid in reaction.

Coal soot makes a black or gray sputum.

Fibers and pieces of lung tissue indicate a cavity.

Fibrinous casts indicate fibrinous inflammations. These are frequently found in croupous bronchitis.

Rectal Alimentation.

Huber has recently shown by actual experimentation, that from fifty-eight per cent to seventy per cent. of fluid egg albumen may be absorbed from the rectum without peptonization. A slightly larger proportion of albumen was absorbed after peptonization, but less than half as much when chloride of sodium was not added. The proportion of salt found necessary to stimulate absorption, was one gramme, or one-fourth of a drachm for each egg.

Diet in Ulcer of the Stomach.

Doctor Roux declares that in ulcer of the stomach, food should be chosen that are digested in the intestines, such as milk, eggs, starches, fruits, and green vegitables; farinaceous substances and eggs should constitute the chief diet. Lentils are preferable to potatoes and beans; among green vegetables salads are excellent; green peas, turnips and carrots should be mashed before eating. Light puddings are easily digested, especially if they contain eggs.—*Journal d' Hygiene.*

Vomiting of Pregnancy.

A writer in the *Lancet* says: "I have not failed once for many years, by a single vesication over the fourth and fifth dorsal vertebræ, to put an end at once to the sickness of pregnancy for the whole remaining period of gestation, no matter at what stage I was consulted. The neuralgic toothache, and pruritis pudendi of the puerperal condition yielded as readily, and to one application."

Beta-Naphthol in Typhoid Fever.

The author, Dr. Petresco (*La France Med.*,) has treated 647 typhoid cases with Beta-naphthol, alone or associated with quinine sulphate,—the former in doses of 3–4 grammes (45–60 grn.) daily, and the quinine in the daily dose of 1–2 grammes (15–30 grn.) He prescribed, instead of water, lemonade containing $\frac{1}{2}$ per cent. of sodium benzoate, or $\frac{1}{10}$–$\frac{1}{8}$ per cent. of benzoic acid. In the grave ataxo-adynamic forms, he applied wet packs. The author has arrived at the following conclusions:

1) Typhoid fever treated from the beginning with beta-nayhthol, can be mitigated and even arrested.

2) The proper dose of naphthol is 3–4 grammes (45–60 grn.) pro die, administered in twelve cachets at hourly intervals; this dose to be repeated every day until recovery sets in.

3) This treatment arrests the phenonema of auto-intoxication or secondary infection. The malady follows its natural, cyclic course.

4) This treatment is incompatible with that by alcohol or alcoholic beverages, since alcohol is a solvent of beta-naphthol.

The Effects of Quinine on Pregnancy.

A collective investigation of this subject is published in the *Indian Medico-Chirurgical Review* for February, 1894, the results of which are as follows:

1. The existence of pregnancy is no bar to the administration of quinine.

2. For fevers and other affections during pregnancy in which quinine is indicated the effects of the drug are more marked than those of any other.

3. That abortion following the administration of quinine is either the result of the original malady or the effect of idiosyncrasy.

4. That allowing for an idiosyncrasy, in cases in which a tendency to abortion exists, and in others as a matter of precaution, quinine is best administered combined with a sedative (opium).

5. Hence the old-standing view of the action of quinine on the duration of pregnancy is not borne out by the clinical experience collected in the replies.

The Nature and Treatment of Acne Vulgaris.

D. Philippson (*Therap. Monats.*) Nothing absolutely certain is known as to the origin of acne or the causal process which leads to stoppage of, and inflammation in and about the glands. As Dr. Philippson points out, the treatment is consequently symptomatic. In those severe cases which are characterized by cutaneous and subcutaneous abcesses, by the formation of cysts with thread-like contents, and the production of irregular, disfiguring scars, surgical treatment is the best. Enclosed suppurative foci should be opened and the contents squeezed out, indurated tissue be incised, and strong (50 per cent.) salicylic acid plaster applied to keep the incisions open. Compresses of aq. plumbi and acetate of aluminium may also be used with advantage, as they thoroughly soften the tuberous parts which have been incised, and by causing them to retrogress make the pustules disappear. For acne of the second degree (Philippson distinguishes three degrees), *i. e.*, when there are numerous comedones and nodules, pastes should be used containing soap, salicylic acid, beta-naphthol, resorcin, sulfur, etc. The following formulæ are employed in Lassar's clinic (*Prov. Med. Jour.*)

1. Beta-Naphthol..... ..... 3j
   Vaselin flavi
   Saponis viridis..... ..āā 3ij.
   Sulfuris Præcip..... 3v.
   M f. pasta. (Lassar.)
2. Beta-naphthol
   Camphor trit.
   Vaselin flavi.....āā 5j.
   Pulv. cret. alb..... 5ss.

St. Louis Med. and Surg. Jour.

Dr. Octinger, of Paris, has been carefully investigating the effect of treating small-pox patients in the dark, at any rate in light entirely deprived of actinic rays, as in a photographic laboratory. The windows were fitted with red glass, the doors guarded by thick curtains, all artificial light was excluded, except that of a photographic lamp with red and yellow glass, the latter only being used in case of absolute necessity. The conclusions arrived at are that so far as concerns the evolution of the primary disease the darkness has not shown itself to be in any way an efficacious treatment of small-pox, but that it is certainly a therapeutic means of considerable effect against the eruption. This developes more rapidly and although pus is formed it dries up more quickly and one escapes not only the ugly cicatrices, but the accidents arising from suppuration are considerably diminished. In a word, the darkness as a therapeutic agent in small-pox is above all a local treatment.—London letter in *Chicago Clinical Review.*

Seasickness.

After a recent voyage, seasickness is a subject which naturally comes up. It may be to others, as it was to me, a kindness to draw attention to a series of articles which appeared recently in the *New York Medical Journal* entitled "Recent Studies in Naupathia, or Seasickness, Symptomatology, Diagnosis, Pathogenesis, and treatment by a New and Efficacious Method." It was written by Dr. Winslow Warner Skinner, who, as ship's surgeon on several trans-atlantic lines, had taken advantage of many opportunies to study the diseases. A complete synopsis of his paper is too long to insert here, but the conclusions upon the pathogenesis and treatment are of most interest. They are as follows:

"1. The principle symptoms of naupathia result from the lowering of the patient's arterial blood pressure. This is a condition *sine qua non* of their development.

"2. Seasickness in a person otherwise healthy and not to aged is *promptly curable* in the vast majority of cases.

"3. Even in aged persons, or in persons having certain affections of the circulatory apparatus, there is often amelioration of the general condition by the employment of the new method of treatment.

"4. The treatment consists in the hypodermic injection of from half a milligramme to a milligramme of atropina sulphate, associated with a milligramme of strychnine sulphate (or nitrate,) dissolved in a cubic centimeter of distilled mint water.

"5. The administration of these eminently toxic substances demands a great degree of attention, prudence and supervision on the part of the physician, who alone should be the judge of the opportunity of their administration and of their dose in each individual case. Given at proper times and in suitable doses, however, no harm whatever will follow their administration. London correspondent *Cleveland Medical Gazette.*

Salycilate of Soda in Tonsilitis.

This remedy is recommended as little less than a specific in acute cases. It should be given as early in the attack as possible and in sufficient doses to cause ringiug in the ears. Fifteen grains every three hours will usually cause this effect, when the dose may be diminished to 10 and then to 5 grains at the same intervals. It should be continued for a day or two after disappearance of the fever.—*N. C. Med. Jour.*

IVY POISONING will soon be seasonable; and while it is well for people who resort to the country during the summer to be careful while they pick wild flowers, it may be of use to them to know that, according to a series of cases recently reported by J. Abbott Cantrell, M. D. (*Philadelphia Polyclinic,*) Labarraque's solution (solution of chlorinated soda) is an excellent remedy. It should be applied in full strength by means of a pledget of lint or of diaper cloth, kept constantly wet with the liquid. It will effect a cure in from three to five days.—*The Sanitarian*

The Blood in Melancholia.

The author examined the blood of twelve patients and the analysis gave the following results:

1. In acute or chronic melancholia there was a marked diminution of the number of globules; in very few cases the percentage approached the normal. Hemoglobin was reduced in the same proportion.
2. A number of cases show considerable curvation of the globules, becoming less marked after a tonic course.
3. Systematic tonic treatment is very efficacious in the treatment of this form of insanity.

The administration of iron alone or combined with quinine and strychnine seemed to answer best. It showed that although melancholia cannot be produced by poverty of blood, yet that the latter is always associated with the former and the improvement in the symptoms coincides with the improvement in the general health and quality of the blood.—*Omaha Clinic.*

Treatment of Laryngeal Phthisis.

Dr. Hajek presented a patient with laryngeal tuberculosis upon whom he had tried a new treatment. The infiltration of the epiglottis was so great that the man could no longer swallow. Dr. Hajek removed the entire epiglottis by means of a galvano-caustic loop, and treated the wound with lactic acid. Four weeks later the patient was able to swallow with ease. Since then he had curretted one of the vocal cords which was ulcerated. This was also dressed with lacit acid and healed readily. It is now one year since the epiglottis was extirpated, and the cure is maintained. The patient has increased in weight 19 kilogrammes (38 pounds), proving that his general condition is better. Dr. Hajek stated that he had already extirpated the epiglottis of three patients. The operation is easy, and there is no great danger of hemorrhage. It is indicated in cases of infiltration or circumscribed tumors. The case proves, besides, in his opinion, that the prognosis of laryngeal phthisis is not so grave as one would suppose.—*La Semaine Medicale in Southern Practitioner.*

The Treatment of Eczema of the Ear.

A brief note in the *Journal de Medicine de Paris* gives the following directions. In moist eczema of this region, where the eruption is confluent and behind the ear or in the auricle, it is well to wash the parts with a very weak solution of bichloride of mercury, which should be warm. This should be done three or four times daily. After the parts are thoroughly disinfected, they may be dressed by an application of iodol, the auditory canal being closed by a pledget of absorbent cotton. This treatment is very useful in those cases where a discharge from the middle ear has produced irritation. In dry eczema in this region we may also use the mild bichloride wash, and follow it by an ointment composed of,—

℞ Iodol.....gr. xv.
Lanolin.....ʒi.

If the disease involves the external auditory canal, the desquamating epithelium should be removed by some absorbent wool twisted upon an applicator, and the canal anointed by,—

℞ Iodol.....gr. xv.
Paraffin oil.....ʒi.

The introduction of a tampon of wool will do much towards the keeping of the liquid in the canal. This dressing should be renewed night and morning. Often a cure results in a very few days.—*Therapeutic Gazette.*

Guaiacol as an Antipyretic.

Friedenwald and Hayden report a series of cases in which they have used guaiacol for this purpose. They think they are justified in concluding:

1. That this drug has a powerful antipyretic action, occasioning a reduction of from one to four degrees of temperature in from one to four hours.
2. That in all cases this reduction of temperature is accompanied by profuse diaphoresis, which may or may not be accompanied by a chill or chilly sensation.
3. That great exhaustion is frequently produced.
4. That the effects may be obtained from comparatively small doses (from 30 to 50 drops), and that great care should, therefore, be exercised in the use of the drug. The drug should be applied but once or twice daily, and the initial dose should not be above 30 drops.
5. That the effect produced by guaiacol, though more powerful, is the same as it obtained from most of the other antipyretics of the coal-tar series, and that the same care must, therefore, be exercised as with the other preparations. Its effect differs widely from the stimulating cold bath in being depressant.
6. That the main indication for its use is in diseases accompanied by high fever in which the cold bath cannot be applied. It may, therefore, be especially useful in typhoid fever as well as in all other diseases accompanied by high fever in which irritability of the stomach prevents the use of other antipyretics.—*Therapeutic Gazette.*

The Death Test.

Chas. Bouchard declares a certain, simple, and easily applied means of recognizing the presence of death is to ascertain the temperature in the axilla; if this falls below 68° F. it is an undubitable sign that life is extinct.—*Med. Age.*

The Germicidal Action of Gallanol.

A recent number of the *Lyon Medical* contains the report of a series of exhaustive experiments by MM. P. Cazeneuve, Rollet and Nicolas, to ascertain the germicidal value of gallanol. The action of the drug was tested on five microbes—that of anthrax, the staphylococcus aureus, the bacillus pyocaneus, the Eberth germ, and the bacilli coli communis. The experimenters arrived at the conclusions that gallanol in excess completely destroyed the vitality of the micro-organisms, that in a relatively weak solution their development was diminished, and that in an attenuated solution, while their growth was not materially affected, their pathogenic powers were destroyed. It was shown that the drug was an invaluable remedy in the vegetable parasitic diseases; while destructive to the micro-organisms, it was perfectly non-toxic to the general system. Gallanol possessed such active germicidal properties that there was no doubt that it could be employed with great benefit in the infectious diseases as an abortive remedy.—*N. Y. Med. Journal.*

Senile Forms of Multiple Neuritis.

Oppenheim (*Berliner klin. Wochenschrift,*) reports six cases of multiple neuritis in persons between seventy and eighty-two years of age. There was a gradual impairment of motion and sensibility of the extremities. They all had a high grade arterial sclerosis. On the fingers and toes there is paresthesia, with paralysis of the interossii and atrophy of the peroneii. Over the nerve-trunks there was slight tenderness, no pain. There was no disturbance of the reflexes. The cerebral nerves were also intact. There was slight anesthesia. Two of the cases improved markedly, a third slightly, one became worse, and the other two remained stationary. This form of neuritis is distinguished from others by the absence of any toxic or infectious cause; its chronic cause, the slight diminution of sensibility, and mild paralysis, and the freedom of the cerebral nerves. The cause is probably a process which partakes largely of the nature of arterial sclerosis. The therapy is wet packs, galvanism, rest, and full diet.—*University Med. Magazine.*

Treatment of Vomiting of Pregnancy.

Lutaud (*Revue Obstetricale et Gynecologique*, February, 1894) states that vomiting of pregnancy is best treated by cocaine. The action of this drug is often strengthed by combining it with antipyrin. Thus the following prescription:

℞ Chlorohydrate of cocaine.....gr. iss.
Antipyrin.....gr. xvi.
Distilled water.....℥iv.
Sig.—One teaspoonful every half-hour until vomiting ceases.

If the stomach will not tolerate this quantity of liquid, ten drops of a one and a half or two per cent. solution of cocaine are administered, repeated at one or two hour intervals.

At times the application of cocaine to the os is extremely valuable.

The following prescription may be used:

℞ Hydrochlorate of cocaine.....gr. xvi.
Extract of belladonna.....gr. iv.
Vaseline.....℥ss.

Cotin's method of dilating the os with the finger sometimes causes immediate cessation of vomiting. Occasional success will follow Routh's procedure, which consists in exposing the uterine neck by means of a speculum and painting with tincture of iodine. In cases of moderate severity, the following mixture will be found serviceable:

℞ Tincture of iodine.....℥ii.
Chloroform.....℥ii.
Sig.—Five drops night and morning at meal times, taken in Seltzer water.—*Therapeutic Gazette.*

The Treatment of Varicose External Hemorrhoids.

When uncomplicated these hemorrhoids never require an operation. The patient's bowels should be carefully regulated; he should avoid prolonged sitting at stool. After each operation and at bedtime he should lie down upon his side and apply firmly to the parts a sponge frequently dipped in ice water. After this he should apply an astringent ointment spread upon a piece of soft lint, and retain it in position throughout the night. I have found no ointment better than the following.

℞ Ung. belladon.,
" stramonii,
" ac. tannici, } .....āā ℥j. M.

Under this treatment they will disappear and the patient's anus become as well as ever.

If from any complication, such as fissure or some other variety of piles, an operation should be necessary, these varicose hemorrhoids may be operated upon at the same time by excising the more prominent portions of the varicosities either by scissors, crushing or the clamp and cautery. The latter method is quite painful in these cases, owing to the involvement of the cutaneous tissue. I have frequently cured this variety of piles by making cross sections of the ring of veins at several points with the Paquelin knife heated to a dull red heat; the subsequent pain, however, is a serious objection to this method. The operation by crushing is much less painful and equally effectual. I have not tried puncturing the tumors with a fine-pointed Paquelin tip, as advised by Dr. Kelsey, having heard of several cases of abscesses produced by this method.—J. P. Tuttle, M. D., in *N. Y. Medical Journal.*

The Early Diagnosis of Cancer of the Cervix Uteri.

The *British Medical Journal* for May 12th gives a report of an address delivered before the Southeastern Branch of the British Medical Association by Dr. Ernest Herman, of London, in which he says that the early diagnosis of uterine cancer is important, as secondary growths occur later and more seldom with cancer of the uterus than of any other part of the body, and, if it is removed, there is a better prospect of freedom from recurrence than in any other form of the disease. Modern improvements, he says, have made it possibly to remove cancer of any part of the uterus, so long as it is limited to this organ, with little risk, but to be successful it must be limited to the uterus. Cancer of the vaginal portion begins in a part that can be felt and seen, and it can be diagnosticated earlier than any other form, and therefore ought to be more successfully treated; cancer of the cervix spreads more rapidly beyond the uterus than the other form, and is less amenable to treatment. This disease occurs chiefly toward the end of the child-bearing period, but it has been seen in childhood and in extreme old age, and therefore the patient's age should not influence the diagnosis in the least. A tendency to cancer is sometimes hereditary, but this should not have the slightest weight, as only a very small proportion of patients inherit the disease.

The first symptoms of cancer are usually hemorrhage and leucorrhœa; pain and wasting come later. The early diagnosis is so important, says Dr. Herman, that any unusual hemorrhage or discharge in a woman who has had children is a reason for vaginal examination, for it may be the first symptom of cancer, and the nature of this disease cannot be determined without local examination. In considering the local signs, the features which distinguish cancer in any part of the body must be taken into consideration.

When cancer begins as an outgrowth from the surface it may look like a growth of warts, or papillæ, or granulations on the vaginal portion, and the surface feels uneven or even rough. It may begin also as an ingrowth beneath the surface. It can be detected by an angry, livid red spot the surface of which is at first quite smooth. This angry color depends upon the vascularity caused by the new growth and upon its tendency to break down, which leads to minute hemorrhages into the growth before the breaking down is extensive enough to make a breach of the surface. The livid surface of a cancer spot bleeds on being rubbed, so that a smooth, dark red spot, bleeding on contact, is very suspicious. This is the earliest stage of cancer, and if there is a nodule that can be felt, the suspicion is still stronger. If the cancer has so advanced as to form a growth like a mushroom or a cauliflower, the diagnosis can scarcely be doubtful.

With regard to microscopical diagnosis, Dr. Herman thinks that the value of the microscope has been overestimated, and that to rely upon its use may lead to many mistakes. It may now and then, he says reveal cancer in a doubtful case, but negative microscopical evidence should never be trusted.

Treatment of Diabetes.

In the *Indian Medical Gazette* for March, 1894, Fermie writes that in treating diabetes it ought to be borne in mind that a dietetic treatment of an appropriate kind is most important, more especially in middle-aged people, and this bears out the rule of Prout, who laid it down long ago that "diet is the first and chief point to be attended to."

The diet ought to be so regulated as to prevent sugar being formed from the food, so that all sugar-forming food must be prohibited. This prohibition should be gradual and not abrupt. Its place, however, must be supplemented by assimilable oil or fat food, such as cream, cod-liver oil, butter, cheese, fat bacon, ham and meat to any quantity, except liver.

Too much milk should not be allowed, nor should pastry, potatoes, beet-root, puddings, and farinaceous substances be allowed at all. The highly-advertised diabetic foods, if really prepared, as stated, without starch, will be very beneficial, and will supply a want long felt in filling up the gaps made by the prohibition of articles of food which long use has made almost indispensable, and renders the patient less discontented with the task set before him and more amenable to treatment. The gluten and almond biscuits prepared for the victims of diabetes are so pleasant to the taste that invalids require no encouragement to use them. Diabetic food may also be sweetened with saccharin tabloids.

It is necessary to regulate the drink as well as the food of diabetic patients. Water should only be drunk in moderation, while chocolate, sweet ales, cider, and all sweet and sparkling wines should be forbidden; in fact, it is inadvisable to take alcohol in any form.

So far as drug treatment goes, there is none which may be termed consistently satisfactory. Codeine certainly, in combination with a strict diet, has a beneficial result. It may be given in ¼- or ½-grain doses three times a day at first, then less frequently. Dr. Mitchell Bruce thinks that opium or its derivatives should not be used until the full effect of a strict diet has been tried; but clinical experience goes to show that codeine can and ought to be given coincident with a strict diet; one acts as an adjuvant of the other and hastens the process of cure. Professor Fraser thinks that morphine is more effective in some cases than codeine.

Salicylate of sodium is regarded with favor by some, especially in those cases where opium is contraindicated.

In treating diabetic coma, early and thoroughly purging with a large dose of calomel is about the best, followed by stimulents and doses of potass. acetas with digitalis every hour at first and then less frequently.—*Therapeutic Gazette.*

For Diphtheria.

℞ Caffeinae..... gr. xx
Sodii bicarb..... gr. v
Aquae, q. s. ad..... ℥ij
M. Sig.—Apply locally as a spray to the membrane.

Sulfonal Poisoning.

Stern discusses the renal lesions in this condition. An insane woman aged 70 received 1 gramme sulfonal every evening, the dose having to be doubled in a month's time. This was continued for more than three months, with frequent intermissions amounting often to eight days. When the total amount taken was some 150 g. the urine showed a dark color due to hematoporphyrin. The drug was omitted at once. Fatal coma, however, supervened in a week's time. The kidneys were of a pale red color, with smooth surface, and contained deposits of lime salts. These changes were such as might be attributed to advanced age, but the microscope displayed a very extensive necrosis of epithelium, and also minute hemorrhages. These minute changes represent a toxic nephritis, and were unquestionably due to the sulphonal. There was a large gall stone in the gall bladder, and small friable concretions in the scarred cystic duct. Very slight jaundice was present during life. The poisoning occured here, as in other published cases, in a woman, and after the prolonged use of the drug. The obstinate constipation, the age of the patient and the changes found in the myocardium no doubt accelerated the result. During the use of sulphonal the urine should be carefully examined for albumen or formed elements, as when once hematoporphyrin-uria appears the prognosis is unfavorable. In the presence of renal disease the prolonged use of sulphonal should be resorted to with great caution.—*Brit. Med. Journal.*

Epileptic Seizures Suspended.

Larrabee (*Southern Med. Rec.*) calls attention to the frequent suspension of seizures for considerable periods under certain mental influences. He mentions the case of a famous church spire painter, who worked in Louisville, who was an epileptic, and yet could be seen any day suspended upon his airy platform one hundred and fifty feet above the ground. He never had a spell while aloft pursuing his work, but once back upon *terra firma* he would be seized with a fit. So marked in this feature that treatment by a new physician, especially if he be a celebrity, often secures a long immunity from the seizures. The knowledge of this fact should caution us against the belief in the full effectiveness of our therapeutic measures.

SURGERY.

A Word to the Busy Doctors Regarding Hemorrhoids.

In complaints of rectal troubles, make diagnosis before you prescribe If piles, discover what kind, whether external or internal, bleeding or not bleeding, protruding or not protruding. External, inflamed piles require, in a degree, the same treatment as internal, yet the external require an astringent which internal cannot bear. Bleeding piles need different treatment from those that do not bleed, and protruding piles special treatment, especially if they resist reduction. External piles are of two varieties: 1, External tags of skin; 2, venous tumors. External tags of skin, when inflamed, constitute one of the most painful varieties of piles. An ordinary prescription can do but little good. Ointments cannot be absorbed. The application of heat or cold is productive of more positive results; use flaxseed poultices or cloths wrung out of hot water and changed often. If heat is unpleasant to the part, apply very cold water in the same way. If an instringent is necessary, make solution of sugar lead, bowels should be moved daily, salines as good as any. An injection of a quart of cold water will afford some relief. A radical cure consists in the removal of the tumor. Never try to push tumor inside of the rectum. The treatment of internal piles is different from the class just cited. The danger from this class is hemorrhage or strangution; either may endanger life. An indiscriminate prescription of an ointment accomplishes nothing. Far better is an application of cold water, when not protruded, an injection of cold water when not protruded but painful, gives more comfort than all the combination of ointments usually prescribed. If, when the person who is troubled with the protrusion of internal piles is directed to take a cold water injection every morning, to move the bowels, to bathe the pile tumor in cold water after an evacuation, annoint the mass with plain vaseline, then push it back, and under no circumstances to use paper as a detergent, much comfort will be gotten out of these directions. If internal piles both bleed and intrude, a little different treatment is used

The hemorrhage must be looked to; when protruding an examination can be made, and if no bleeding points are found the following will be found good:

℞
Vaseline ..... oz. j.
Acetate lead ..... gr. xx.
Pulv. opii ..... gr. xv.
Balsam Peru ..... dr. j.

M. et. Sig.: Apply to pile after washing with cold water.

If protruding external piles are accompanied with much pain, some complication exists, usually ulceration. Washing with hot water will be found more agreeable, to be followed by the following prescription, which contributes much to relief:

℞
Cocaine ..... gr. vij.
Ex. opii ..... gr. xx.
Ext. belladonnæ ..... gr. xvj.
Lanoline ..... oz. j.

M. et Sig.: Apply after washing. Then return mass.

At bedtime use the following suppository:

℞
Iodoform ..... gr. iv.
Morph. sulph ..... gr. ½

M. Ft. sup. No. i. Sig.: Insert at bedtime.

Itching is often mistaken for piles; if itching is a most prominent symptom, it will most likely be found to be pruritis. If with piles we have an itching of the surrounding parts, the following is suggested:

℞
Vaseline ..... oz. j.
Ichthyol ..... dr. j.

M. Sig.: Apply often.

CONTRIBUTIONS TO OBSTETRICS AND DISEASES OF WOMEN.

[NUMBER THREE].

THEOPHILUS PARVIN, M. D.

CHILLS FOLLOWING UTERINE INJECTIONS.

Mrs. R., twenty-nine years old, was delivered of her second child after a normal labor, on April 14th. Her condition continued favorable until the afternoon of the 16th, when there was slight fever and there was also some tenderness over the left iliac region. The fever increased and the next day was so great and, having associated with it a sense of depression and mental confusion, some alarm was felt, and the physician in charge, from whose notes I have taken the preceding facts, and shall take others, had me visit the patient, some twenty miles from the city.

I found she had an offensive lochial flow, a pulse of about 100, and a temperature of nearly 103°. Believing the essential indication was to thoroughly wash out the uterus, I did so, employing for this purpose a fountain syringe and a warm mixture of creolin and water. The irrigation was made without the patient suffering pain, scarcely discomfort. She had been placed across the bed, her feet resting on chairs, for the operation. Thirty minutes after being replaced in her usual position, she had a severe chill lasting ten to fifteen minutes, and her temperature rose to 104°. I ought to state that in the fluid coming from the uterus during the irrigation there was a small fragment of the membranes, and also apparently a piece of placental tissue as large as half a small marble. The fever subsided somewhat on the morning of the 18th, but as the lochial discharge still continued to be somewhat offensive, upon visiting her in the afternoon I believed a second irrigation indicated, and accordingly it was given. This too, was followed by a more violent chill and the temperature soon rose to 105°; but the decline of the temperature was earlier and more decided than after the previous operation. On the 20th, I found her with a high temperature, considerable prostration and the lochia not yet entirely normal as to odor. It seemed to me that there must still be in the uterus some infecting material, and I determined to use the curette, employing therewith corrosive sublimate in the creolin mixture. I found in the discharge that occurred from the washing a partially decomposed clot probably the size of a small marble. Again the treatment was followed by a still more violent chill, and the temperature went above 105°. The fever continued, the temperature varying from 100° to 105° until the 21st, when it almost entirely disappeared. It returned, however, at night and continued through the 22nd; in the evening of that day another chill came during a profuse perspiration following the application of twenty minims of guiacol over the abdomen; the temperature during the chill reached 107°, lowering very soon after the cessation of the chill. The fever continued each morning on the 23d and 24th,

when it disappeared for twenty-four hours; but it returned the 26th, and continued during that and the next day; the temperature, however, was not high, when it entirely disappeared and uninterrupted and complete convalescence began.

REMARKS.

First, a word in regard to the unnecessary use of intra-uterine as an adjective for injections of the uterus. Uterine is sufficient without the awkward prefix; we never think of saying intra-vaginal injections, and yet the term would be equally appropriate with the former.

Next, here was a case of puerperal infection when all requisite antiseptic precautions had been taken by a wise and experienced practitioner; and such cases will occur again, so let us not be in haste to condemn the obstetrician who meets with such accident, notwithstanding all proper precautions.

But the essential point in the history, the sole reason for here presenting it, is the fact that the uterine injection was followed in each case by a chill. This was my first experience of the kind, though I have in many cases made use of such injections.

According to Silvestre, *Les injections intra-uterine, et les accidents provoquès par leur emploi én obstètrique*, 1892, states that generally the chill occurs during the first hour following the irrigation; 20, 30 and 45 minutes represent the intervals usually noticed—in one case the interval was an hour and three-quarters. The decline in the temperature and that in the frequency of the pulse usually take place in 4 to 6 hours, and these diminutions are never delayed more than half a day. According to this author too, the chill is independent of the fluid injected; it has occurred after the use of carbolic acid, corrosive sublimate, thymol chloral. A chill has followed a prophylactic injection.

Therefore the hypothesis asserted by Sylvestre, that the chill is caused by uterine contractions, excited by the injection, determining the entrance of septic products in the uterine blood and lymph-vesseis into the general circulation, is scarcely tenable in view of the fact last stated.

Kaltenbach has briefly referred to this accident, stating that the cause is not at [illegible]ear, but suggests, in addition to entrance of septic stuff into the blood vessels, the possible entrance of some of the injected fluid, and also the destruction of blood corpuscles. He further states that usually the chill has no unfavorable significance.

Can we prevent the chill? It has been suggested that the reservoir of the fluid irrigating the uterus should be held only a few inches higher than the patient's hips. It is hardly necessary to insist upon the importance of having a free exit for the fluid from the uterus. I have generally employed the catheter of Bozeman as modified by Fritsch; but there are several other instruments equally good, some of them possibly better, and among these may be mentioned that of Doléris, which I have occasionally employed.

There is possibly a special lesson to be learned from the chills in this case. It will be remembered that one of these occurred, though no injection immediately preceded it; it followed a profuse perspiration caused by the application of guiacol. May not all of these chills stand for a particular type of constitution? Are they not the expression of some peculiarity of organization, an intrinsic susceptibility to the action of certain agents or influences? We may call them then, for a want of a better name, nervous chills, and make them, including the elevation of temperature, as has previously been suggested, analogous to similar phenomena occasionally occurring after the use of the catheter or sound. But it is doubtful whether any explanation will prove entirely satisfactory.

Relation of Bacteria to Colds.

A Prof. Schenck, according to the London *Globe*, has recently discovered that what is commonly called a cold is due to bacteria. His theory is that when a person enters a cold room, the bacteria flock to his warm body, and find entrance through the open pores of the skin. We are surprised to find a paragraph going the round of the medical journals, calling attention to this remarkable discovery. The idea that bacteria are possessed of volitionary power and capable of pouncing down upon the body like a flock of vultures to seek out the so-called pores of the skin like weasels, is too monstrous for credence by any one who has the slightest knowledge of medicine.—*Modern Medican.*

EXOPHTHALMIC GOITER.*

W. W. HILL, M. D., Weston, O.

This is a disease of unknown origin, and is characterized by exophthalmos, enlargement of the thyroid gland and functional disturbance of the vascular system.

The etiology is known to you, and I will simply say that it is rare in men. It usually occurs between the age of twenty and thirty, although it is sometimes seen in young girls about puberty. It is sometimes seen in several members of the same family. I will also note a few of the causes of the disease, such as worry, fright and depressing emotions, precede the development of the disease in a number of cases.

In the morbid anatomy no constant changes have been found in exophthalmic goiter. Special attention has been paid to the condition of the sympathetic system, as the rapid action of the heart and dilatation of the vessels have been attributed to paralysis of the sympathetic fibers, particularly the vaso-dilators. This view has found many supporters, but neither in the ganglia nor in the nerves are there any changes which can be regarded as constant and peculiar. On the other hand, many features of the disease are explicable on the ground that it is an affection of the medulla oblongata. Dr. Hale reports a case dying of an acute intercurrent disease, in which there was hemorrhage in the floor of the fourth ventricle. I think the vascular and nervous features must be due to a lesion of this kind, but it is difficult on any theory to explain all the symptoms of the disease and to bring into line the mental and vascular phenomena, the exophthalmos and the goiter.

The symptoms vary in different individuals. The acute and chronic forms may be recognized. In the acute form the disease may develop very rapidly; when the patient is suddenly seized, we sometimes have intense vomiting and occasionally diarrhoea, always rapid action of the heart and throbbing of the arteries. In most all cases we have prominence of the eyes, the thyroid gland enlarged and usually soft.

The characteristic symptoms vary a good deal in their onset. The cardiac and vascular symptoms are usually first to develop, and the patient complains of palpitation and shortness of breath, and on examination we find the pulse increased in force, the carotids throb. In long standing cases the heart may be hypertrophied and the sounds very intense. Exophthalmos usually follows the vascular disturbance. It is readily recognized by the protrusion of the eyeballs and, partly from the fact that the lids do not cover the sclerotics, the protrusion may become very great and the eye protrude from the socket, or it may be barely perceptible. The enlargement of the thyroid usually developes with the exophthalmos. It may be general or only in one lobe, and is rarely as large as an ordinary goiter. Tumor is present in some cases, involving the hands mostly.

The prognosis is unfavorable, or my cases were as I have only been called to treat two and they both died. Before I say anything about the treatment I will give you the conditions I found in a girl fourteen years and seven months old.

On December 20th, 1893, Miss A. V. T., was brought to my office. She complained of pain in her head; she was anæmic and nervous. Temperature normal; pulse beat 100, and there was a throbbing of all the arteries. At this time there was no perceptible enlargement of the thyroid gland. Family history was good so far as I could learn. No hereditary disease on either side of the family. At this interview I learned the girl had menstruated at the age of 13 years, and had always been regular until December 1st, 1893, when she had taken cold by getting her feet wet while at school and did not menstruate. At this time I prescribed tincture of strophanthus to lower the pulse rate. I also gave her iron and quinine to build up the constitution. I directed her to report in ten days, but I did not see her again until January 15th, 1894, when I found the temperature normal and the pulse 96, and she was very nervous. I again prescribed quinine and iron, also tincture of strophanthus, and asked to see her within

*Read before the Northwestern Ohio Medical Association, June, 1894.

the next ten days. I did not see her again until March 22nd, 1894, when I was summoned to her bedside and found her in convulsions, pulse rate 160, and all the arteries throbbing, eye balls protruding so that the lids did not cover the sclerotics. This was the first time that I noticed any enlargement of the thyroid gland; this was a little more marked on the right side. I learned at this time that she had been better and had attended school about a month, that on the 20th of March she had been very badly frightened, and that she ran home a distance of about forty rods and fell onto the floor on opening the door and began to complain right away. I at once told the parents that she could not recover, and that if they wanted counsel to send at once. This was about four o'clock A. M., and at 8 o'clock A. M. Drs. Schooly and Cook arrived. We gave bromide, chloral, chloroform and morphia, but nothing would relieve the spasms, and she died March 22nd, 1894, at 8.30 P. M.

We were not permitted to hold an autopsy and cannot give the condition of the brain, cord and internal organs.

CHRISTIAN SCIENCE AND ITS RELATION TO THE MEDICAL PROFESSION.*

HILDEGARDE H. LONGSDORF, A.M., M.D., CARLISLE, PA.

In appearing before you on this occasion I feel it due myself, as well as this learned assembly, to offer a partial explanation of my purpose, in so doing. For otherwise it would certainly savor on my part of the arrogance of conceit, or an unwarrantable assumption of privilege, to attempt to address on a medical subject, such an august company of veterans and superiors in an art where at most I can only be a tyro.

The papers read here are presupposed to come from those whose skill and knowledge have brought honor and repute to their names and value to their slightest utterance on such topics as habitually arise on occasions like this. Far be it from me to invade such a field, only to illustrate by my temerity the time-worn maxim that "fools rush in where angels fear to tread."

But while the primary object of our meeting is mutual discussion of the more immediately important medical subjects, and instruction from those who are so well able to give it, there are also closely allied and leading up to these, many subjects in the line of suggestion and inquiry which may pardonably be taken by the less gifted.

The subject therefore, which I shall briefly consider here is one of these, not a purely medical subject from this standpoint, but rather one of those related subjects. which, though at first glance insignificant and even contemptible, yet from the proneness of the uninformed to exaggerate and mystify diseases and all remedial agencies—carry with them an overpowering influence, and to the younger practitioner especially, are baffling and vexatious.

Such is Christian Science, probably the most pretentious and certainly the most successful of the out-growths of our modern high pressure civilization; which not content with its acknowledged empire over material nature, and subsidizing the results of scientific investigation, must needs enter the realm of psychological phenomena, and skilfully weaving therefrom a tissue of fact and fancy, spread it before the gaze of a too credulous public, call upon it to believe what it cannot explain, and revere what it cannot comprehend.

There have been many such mock systems in former, as in later years, most of them having for a basis the "divine art of healing," along with other pretentions to a spiritual or philosophical status, all wearing a more or less familiar guise to the reader of history. Christian Science, however, goes a step beyond any of its forerunners, is one shade finer, and more plausible in its theory, and more conspicu-

*Read before the Medical Society of the State of Pennsylvania, 1894.

ously successful than any similar intellectual epidemic the world has ever witnessed. It seems to unite and intensify into some semblence of symmetry, something of the astrology and prophetic hallucination of the ancients; something of the religious ecstacy and mysticism of the middle ages; something of the progressive thought of the later school of the English scientists, and welding them together by the despotic power of that prescient imagination which overleaping the bounds of demonstrable truth, presents the result to the conservative thinker of to-day, as a reasonable doctrine, no less a universal panacea for "all the ills that flesh is heir to." These fatuous misbeliefs are the intellectual scandal of our age, and while we must desire to apply some corrective influence, it becomes a puzzling question how to regard those who honestly believe in them and what should be the attitude of the physician toward such as aspire, under its provisions to the office of "healers."

In more accurately defining christian science, I would observe, that it must not be confounded with hypnotism, animal magnetism, faith or mind cure, spiritualism, clairvoyant or other trance, or the old-time powwowing processes which the practitioner in country districts still frequently encounters. All of these it somewhat resembles, having apparently some family features of all, yet differing in essential particulars. Christian science pure and proper, disclaims or ignores these agencies and claims a Heaven-derived power of its own; and in this probably lies its greatest influence—for in all times a "divine right" stoutly asserted and skilfully maintained, has held its own against reason, logic and the evidence of the unprejudiced senses. There is no instinct so universal as that which responds to the intimations of the supernatural, and the most realistic among us must acknowledge this influence as a factor in certain diseases. We see it exemplified in the history of the earliest nations, and there we attribute to ignorance, but the candid student must admit that the advanced intelligence of the later periods has changed the form, but not eradicated the inherent tendency.

To the primitive man death and disease appeared the immediate act of some invisible, but all-powerful being, who from malice or rage or other human passion, dealt out dire punishment upon mortals. Hence his favor was sought and propitiatory rites and ceremonies were observed to avert disaster and suffering. But this is not to be wondered at. The ignorance of the ancients as to the true character and real origin of disease appropriately correspond with their ignorance of the constancy of the phenomena of the external world. Subsequently, while the more cultivated and advanced nations were passing through the throes of a mighty religious revolution and the dismemberment of social structures was everywhere imminent, a further development of this natural attitude of man toward a Creator and the universe took place, and a thousand abnormal manifestations of mind over matter were attested, until a mystical system —partly real and partly fanciful was evovled. Under this system many delusions were experienced, by such as might be called honest believers, while jugglers and magicians in all fields, but especially so in those allied to the curing of disease, were rife.

Following the renaissance of art and literature, knowledge grew, and it may be that with a more general diffusion of the underlying principles of medical science, such as the uneducated mind can grasp, and a clearer apprehension of the import of recent discoveries in bacteriology and similar fields of investigation, the demonstrations which are now so constantly made to lead the masses back to the twilight ages, in this respect, will cease. But until this more general intelligence shall come to pass, we will doubtless continue to witness the phenomena of the blind gaining instant sight, the lame being made to walk, and the suppurating sore healed by a word; such alleged cures being regular occurrences in the vicinity of a properly qualified christian scientist. From these centers of abnormal experiences, ever widening influences diverge, and we shortly see vast numbers of enlightened and cultivated persons of both sexes and of every shade of religious belief, accepting and propagating the ideas that form the basis of the popular manifestation.

Christian science shrewdly appreciates the value of this prevailing tendency of human nature, and therefore, as its name imports, it is found to be a compound of

theology and *the art of healing*—in these two sides expressing the strongest wants of mankind. Otherwise it calls itself the "Science of Health," and an elaborate treatise has been given to the public for the purpose of explaining its peculiar doctrines or principles, and setting forth the benefits which must accrue from its universal acceptance.

It was *discovered*, as its adherents put it, in the year 1866 by Rev. Mary Baker G. Eddy, of Lynn, Mass. In giving an account of her discovery and preliminary experience, Mrs. Eddy says that she was impelled from childhood "to seek diligently after God as the one great ever present remedy for all human woe." She states that the physical side of this research was aided by hints from homeopathy, to the conclusion that *mortal belief*, instead of the drug, governs the action of material medicine. She found in the remedies enumerated by Jahr that the prevading secret was that "the *less* material medicine we have the better the work is done," and she proceeds to prove that this is so by an illustration from this school of practice. "One drop of the thirtieth attenuation of Natrum muriaticum in a tumblerfull of water and one teaspoonful of water mixed with the faith of ages would cure patients not affected by a larger dose." The drug disappears in the higher attenuations of homeopathy, and *matter* is thereby reduced to the proportion of mortal mind, but the curative principle remains and is found to be even *more* active.

She also relates her own experience, while in failing health, with a distinguished mesmerist. His method of treating her was by *manipulation* and water, and although she acknowledges that he had advanced views along his own line of research, she pronounced "mind cure on a mental basis" a kingdom divided against itself.

In a similar manner she argues against the efficacy of animal magnetism. It is interesting to note the elimination of her own peculiar idea from the prevailing influences of the times and her final success in reaching a standpoint *differing* from all her predecessors and thus gaining *originality* and *potency* for her cause. It must be confessed that there is something beautiful and attractive in the ideas thus expressed, and the most fastidious among us could take no exception (on the ground of ethical mortality) to the tenor of her sentiments.

In her conclusions the odium of hypnotic experimentation is eschewed; the ridicule attaching to clairvoyant and other mediumistic practices is avoided. She demonstrates in fact, the spiritual attenuation of a noble idea, more subtle and dilute than any homeopathy ever propounded; a methaphysical abstraction more elusive and begiling than any hypothetical figment portrayed in the pages of German philosophies; while there lingers about her doctrine a classic flavor not unworthy the noble parentage of Plato, who first taught the theory of Ideas or Essential Forms.

Each one of these was at once the prototype and the cause of a number of transitory existences in the sphere of the sensible. To these ideas, as to higher realities, phenomena were referred, and their explanation found in them by Platonism. Following along this line of suggestion, which every classic student has conned, we perceive that modern christian science is a restatement of an ancient principle, which has lived in and influenced metaphysical speculation in all ages.

Mrs. Eddy tabulates her theory on the understood dominance of supernatural *dread* or *fear* in most people, and at the same time skilfully evades direct issue with superstitious antagonisms, by calling *fear* another name for disease. She declares that "war is waged between the evidences of spirit and the evidences of the five physical senses." "Divine science was against *sin, sickness* and *death*." And again, "All sensation is *mind* and mind is *God*," and further "The notion of more than *one* mind is unsatisfying and unscientific." Her deduction, therefore, is that *mind* is synonymous with *Good* or *God* and per consequence. All else is *material* and not to be considered.

Thus she directs the following formula. "Science saith, to all manner of disease, know that God is all-powerful and ever-present, and the sick are healed." Other statements embodying this *science*, so-called, are made in the extraordinary book called "Science and Health," which is in a sense the Pharmacopeia of the new school, but it is on the basis of the foregoing that their practice is built up.

The patient is taught that sickness is a

belief, a *latent fear* made manifest on the body in different forms of disease. "This *fear* is formed *unconsciously* in the silent thought, as when you waken from sleep and feel ill, experiencing the *effect* of a fear, whose existence you do not realize." But if you "fall asleep conscious of the Truth of Science, viz., that man's *harmony* is no more to be invaded than the rythm of the Universe, you cannot awake in fear or suffering of any sort." Thus christian science aims at the highest medical ideal, the prevention, as well as the cure of disease. That *matter* cannot suffer was illustrated in a very simple manner by a very intelligent lady, a friend of mine, who while on a visit to the West, was lead to investigate, and finally become a convert to christian science. She said with much apparent conviction, "why if you would cut off your hand and throw it on the floor, it couldn't feel." "It is only your mind which is *spirit* that feels and *spirit* which is *God* cannot be diseased or suffer." So the whole belief in disease is *unreal*, a fantasy, the result of erroneous teaching, or latent fear, or sin.

This, then, is the whole doctrine. Comprised in these somewhat enigmatical and contradictory statements, is the motive power of a system which has more strength than most of us would be willing to believe. If it were not for this fact, that it is rapidly spreading, gaining friends and influence among the most intelligent classes, we might well dismiss the subject with a smile; as one more of the numerous phases in which the ever-restless mind, ever recurring to the unknown, ever tracing its circling course upon itself, seeking to find the cause from the phenomenon, has manifested itself.

But it has a vast and increasing power and not only among the uneducated. It has its representative literary journals, a system of propogating its tenets by phamphlets and tracts and books. It has an array of special agents or missionaries, a respectable showing of institutions or metaphysical colleges, extending over many of the different States, and a vast number of private establishments for the cure of every disease under the sun. Preaching and teaching come into the plan and to a thoughtful observer it seems as if the dark ages, when demonology and magic ruled the court, the camp and academic grove, were about to return.

It is, as we have seen, an old acquaintance with a new face, and its extraordinary progress has doubtless been due to the reactionary tendancy of the times among a large class of orthodox people, from the scientific materialism, naturally growing out of the demonstrations going on here and abroad, as to the cause and prevention of disease.

The question arises how we are to regard it and how we are to be armed against its inroads. If mental force has a therapeutic value, if the mind can control not only the kingdom which of right belongs to it, but also the laws of matter and of physical sense, then it seems as if our resources were inadequate, and some form of definite action should be taken whereby we could cope successfully and with dignity, with what must otherwise be a dangerous foe.

It would be out of place to argue against the possibility of mental cures. Thousands of such instances are upon authentic record and it would be idle to deny the power of the mind over the body. There is no question that certain diseases have been cured by believers in faith cure, in prayer cure, in every phrase of this theory that can be imagined. There is such a healer near my home, who has hundreds of patients, from near and from far they come, and I do not doubt that some are cured, and to a rational thinker there is no mystery about the process, but the fact remains that the process cannot be rationally explained, so that the subjects of it can clearly understand it. Consequently in endeavoring to maintain our professional self-respect, we are in danger of actually becoming illiberal, narrow-minded and dogmatic.

The importance of some definite restraining force for these abuses can scarcely be overestimated, and if public opinion and the advanced philosophical science of our era have been powerless to effect this, it would seem to come into the province of legislative enactment.

CONTRIBUTION TO THE SURGERY OF THE GALL-BLADDER, WITH REPORT OF THREE CASES OF CHOLECYSTOTOMY AND ONE CASE OF CHOLECYSTENTEROSTOMY.*

X. O. WERDER, M. D., PITTSBURG, PA.

There are practically only two operations to be considered for the relief of cholelithiasis, the most common affection of the gall-bladder requiring surgical interference, namely, cholecystotomy with suture of the edges of the gall-bladder to the abdominal wound and cholecystenterostomy. Cholecystectomy, on account of the greater mortality attending it as compared with these two other operations, is, in my opinion, only applicable in malignant disease of the gall-bladder, or when this viscus has become so contracted as to make either of the two operations technically difficult or impossible. Cholecystotomy, with complete closure of the incision and return of the gall-bladder into the peritoneal cavity, still advocated by some operators, and called "ideal cholecystotomy" is equally objectionable for the same reason of greater mortality.

Generally speaking, the technique of both operations, cholecystotomy and cholecystenterostomy has been so much improved and the results of either proven so satisfactory, that a kind of rivalry has arisen between them; and since the introduction of the "Murphy Button" it almost seems as if the latter was destined to supersede the former. The principal reason of this is the fact that cholecystotomy is not infrequently followed by a permanent, or at least, a long persisting fistulous opening between the gall-bladder and abdominal wound, accompanied by a more or less constant stream of bile pouring over the abdomen, which is not only a source of annoyance to the patient on account of the inevitable soiling of the clothing and by giving rise to eczematous eruptions and dermatitis, but it may, when the greater portion of the bile is turned out of the system through this external sinus, become a serious menace to health and the life of the patient, because a certain quantity of bile, as we know, is necessary to carry on the digestive functions properly.

By means of the "Murphy Button," cholecystenterostomy has not only become a remarkably simple and easy operation, but judging from the uniformly successful results published within the last few months, it appears to be one of the safest operations in abdominal surgery. It is, therefore, not at all surprising that Murphy, the ingenious inventor of the anastomosis button, and his followers have been decidedly partial to cholecystenterostomy in all cases in which operation is indicated, when we consider that both operations are about equally safe, and that the latter has the advantage that it does away with the not uncommon sequela of a biliary fistula and establishes at once a new channel from the gall-bladder into the intestinal canal, through which even the largest calculi find a ready passage into the bowel, and that it obviates the necessity of scrupulously searching the common duct for any obstruction for the purpose of removing it. I am not aware of any unpleasant after-effects in the cases operated on, up to the present, but the operation is a new one, and the patients have scarcely been under observation a sufficient length of time to allow of any definite conclusions. It seems a matter of considerable importance to me, to make the anastomosis as closely to the normal communication, by means of the common bile duct, as possible. For this reason the duodenum, or, at least, the upper portion of the jejunum, should be selected. If, for some reason, this part of the intestine cannot be brought into view, as happened to me in case No. III, cholecystotomy, at least in uncomplicated cases, seems preferable.

The cases reported in this paper are three cases of cholecystotomy and one case of cholecystenterostomy, all followed by recovery. The operation of cholecystotomy was performed in two cases for cholelithiasis, the number of calculi removed being in one case twelve, in the other sixty-eight, varying in size from a pea to a hickory nut; in the other for

* Read before the Medical Society of the State of Pennsylvania, 1894.

empyema of the gall-bladder. Cholecystenterostomy was done for a permanent biliary fistula with, at least, a partial obstruction of the common bile duct, probably due to a stenosis and adhesions. In two cases (No. I and II) the gall-bladder was completely surrounded by omentum and intestines, so that it became necessary to free some of these adhesions from the anterior surface of the gall-bladder before it could be incised. In both of these cases the walls of the gall-bladder were very much thickened, in one (No 1) not less than three-quarters of an inch, and strong suspicions of malignancy were entertained at the time of the operation, but the patient, now over a year since her operation, is in perfect health.

CASE I.—Mrs. R. W., æt. thirty-nine years; seven children, youngest one year. During her last pregnancy had two, three or more paroxysms of pain in right hypochondriac and epigastric region. After her confinement October 15, had no attacks until the beginning of April, 1892, when they returned at intervals of from four to six weeks, and during the three or four months preceding the operation, these paroxysms came on every week, sometimes even two or three times a week, keeping her confined to bed half of her time. I saw her for the first time six or seven weeks before her operation, when she was suffering from an attack of local peritonit is, compelling her to remain in bed about two weeks with elevation of temperature to 101, vomiting, tympanitis and icterus. Over the region of the gall-bladder a mass could be mapped out exceedingly tender, about three inches long and one and a half wide.

Operation March 22, 1893, at Mercy Hospital. Vertical incision three inches long over seat of tumor; this was found completely covered with omental and intestinal adhesions, which had to be separated in front of the gall bladder before it could be incised. Walls of gall-bladder about three-quarters of an inch thick, exceedingly friable, so that sutures would scarcely hold, suggesting malignancy; they were sutured to abdominal incision. Ducts were found unobstructed. Sixty-eight calculi of various sizes were removed. Rubber drainage introduced and gall-bladder washed out. Fistulous opening closed on tenth day, and patient has remained in perfect health ever since.

CASE II.—Mrs. Agnes K., referred by Dr. J. C. Hierholzer, æt. fifty-three, was suffering for seventeen or eighteen years from burning and tearing pains in the hepatic region, with vomiting at intervals of various duration and treated by different physicians for pleurisy, bilious attacks, neuralgia, etc. Present illness began in March, 1893, with severe pains of paroxysmal character, irregular elevations of temperature, dry tongue, constipation, very severe headache and no jaundice. Marked tenderness over region of gall-bladder, which was distinctly enlarged, reaching about four inches below border of ribs, Operation July 3, 1893, at Mercy Hospital. Usual incision exposed gall-bladder surrounded by omental and intestinal adhesions; these were broken up over anterior surface to make room for incision. Walls of the gall-bladder very much thickened; sutured to abdominal wound; gall-bladder contained several ounces of mucus and pus, but very little bile and no calculi. Rubber drainage tube inserted and gall-bladder washed out daily. Discharged from the hospital completely relieved, but with biliary fistula which closed completely three or four months after operation. at present she is in perfect health; she has a small hernial protrusion at site of operation. This case is interesting on account of the history of biliary colic extending over seventeen or eighteen years, with attacks of local peritonitis and a beginning empyema of the gall-bladder without a trace of any calculi.

CASE III.—Mrs. D., æt. twenty-nine; for over a year had paroxysms of intense pain in epigastrium and right hypochondrium, lasting from a few minutes to several hours, accompanied by vomiting. During the last few months these have returned at shorter intervals, sometimes daily, scarcely less than two or three attacks a week, so that her general health began to fail. Occasionally her conjunctiva was slightly icteric, but there was never any distinct jaundice. The region of the gall-bladder was examined repeatedly, but while always tender to the touch, it was never found enlarged. Repeated examinations of stools proved negative. Her condition became so miserable that we at last decided to explore the gall-bladder. Operation was performed January 28, of this year, at the Mercy Hospital. Gall-

bladder not enlarged and free from adhesions, considerably distended with almost clear fluid. Ducts were free. Wound in gall-bladder attached to abdominal wound and twelve large, hard gall-stones, without any facets, but with rather sharp points, removed. Left hospital February 24, still discharging bile. Discharge gradually lessened, biliary fistula closing up completely for a few days at a time, then opening again, but is now completely healed. She has gained flesh since the operation and is in good health, but is troubled with flatulency, giving her some pain in the epigastrium, which is, however, immediately relieved after a free eructation of gas.

CASE IV.—Miss Bella F., æt at twenty-five, admitted to the Mercy Hospital, April 3, 1893; service of Dr. C. O. Goulding, with the diagnosis of typhoid fever. As typhoid fever, the case was of more than ordinary severity, the temperature reaching 103 and higher for eleven days. April 16, patient was seized with severe pain in epigastrium, followed by vomiting for twenty-four hours. A tumor was noticed two days later in the hypochondriac region, somewhat the contour and about the size of a kidney, not very tender on pressure. During the next few days, tenderness over tumor increased and pains of a lancinating character were complained of. Temperature and pulse still increased.

April 26, under ether narcosis, Dr. C. O. Goulding made an incision over the region of the tumor, which, when exposed, was of a livid color, deeply congested, of oblong shape and fluctuating, extending down nearly to illiac fossa. Not adherent at point of incision, but slightly adherent to abdominal wall over limited area below. Tumor was not incised, but wound was packed with iodoform gauze.

April 28, two days later, during which time patient's condition had somewhat improved, the tumor was opened and about half a pint of viscid, semi-transparent fluid containing pus was removed.

May 1, great amount of biliary fluid discharged since; removed several fragments of gall-stones. Several other stones were removed at varying intervals, the fistulous tract gradually growing smaller in the meantime.

June 5, sinus dilated with laminaria tent and several stones removed; some days later a stone was found occluding cystic duct as shown by a continuous discharge of considerable mucous, but no bile; stone was located three and a half inches from external opening, but all efforts to remove it by forceps or irrigation proved useless.

July 12, she was again anesthetized, fistulous opening enlarged in line of old cicatrix one and a quarter inches. Efforts at extraction failing, the stone was crushed and fragments removed. It was not faceted, almost round, diameter about three-quarters of an inch. Wound was packed with gauze and allowed to heal by granulation. Bile discharged freely after operation. Patient's condition much improved and gained in weight. Fistula was almost closed and patient allowed to go out of the hospital August 24, continuing under observation. For above notes, I am indebted to Dr. C. O. Goulding, her attending physician.

Cholecystenterostomy: Above patient was readmitted to Mercy Hospital, September 8, and through the kindness of my friend and colleague, Dr. Goulding, transferred to my department. Biliary fistula has been discharging a great deal of bile since leaving the hospital, and she is complaining of considerable pain and tenderness over region of liver and gall-bladder and is constipated. She is very anxious to be relieved, not only of her biliary fistula, but of her pain which is more or less constant, and keeps her awake at night. For this reason, after the usual preparations, an exploratory incision was made on September 15, 1893, about four inches in length between the old cicatrix and the median line. The adhesions posterior to the liver were so firm, that the intention of examining the common duct and removing any obstruction that might be located there, had to be abandoned and cholecystenterostomy was performed in the hope that a new free channel between the gall-bladder and the intestine would not only cure the biliary fistula, but relieve her of her pains. The duodenum was so firmly bound down by adhesions, that it could not be brought up; a loop of the jejunum was therefore picked up, the gall-bladder opened near its abdominal attachment, and attached to the jejunum by means of the "Murphy Button" in the usual way. The abdominal wound was closed by silk-worm-gut sutures, and a piece of iodoform gauze

was packed into the old biliary fistula. The patient rallied well from the operation; two hours afterward her pulse was 76 and temperature 100⅘°.

The first two days after operation, a large quantity of bile was discharged through the fistulous opening, and on the third day she showed some signs of jaundice.

September 23, there was some blood mingled with the bile discharged; the skin surrounding the fistula had become slightly eczematous. In the evening of the same day, when the dressing was changed, there was only a very little blood contained in the bile discharged, but it had a distinctly fecal odor.

September 26. The discharge does not contain so much bile as formerly, but seems to consist of mucous and fecal matter tinged yellow by bile. Eczema of skin still very annoying. For fully a week there was quite a copious discharge of mucous and fecal matter, so that the dressings required changing three or four times a day. No rise of temperature since September 23.

October 11. Patient sat up nearly the whole afternoon; during this time the button was passed by the bowels, just twenty-seven days after operation.

October 20. Dressing showed no evidence of discharge for two days; eczema all disappeared; laparotomy wound completely healed; patient is able to be up all day and feels quite well.

Since her discharge from the hospital she has been able to return to her work as a servant girl, and has been in very good health until about three or four weeks ago she feel down a flight of stairs, alighting on her right side over the old cicatrices, which gave rise to considerable pain over the region of the gall-bladder.

In a similar case of biliary fistula, it would be preferable to separate the adhesions between the gall-bladder and the abdominal wall, and place the male portion of the Murphy Button into this old fistulous opening, and unite that with the intestine. This has the advantage that no new opening is required in the gall-bladder, and that the fistulous tract in the skin can be closed at once, doing away with all biliary and fecal discharges with which the convalescence of this case was complicated. The fact that the gall-bladder remains attached to the abdominal wall after anastomosis is made, interferes with its contraction and favors the continuance of the fistula.

Ultimate Prognosis of Neglected Adenoid Hypertrophy.

Dr. D. Bryson Delavan (*Medical Record*) says:

The question is asked, does adenoid hypertrophy, if left to itself, disappear, leaving the vault in a normal healthy condition? Generally speaking, it does not, but remains under some pathological state, which may continue throughout the life of the patient.

The enlargement may not subside, and a degree of hypertrophy sufficient to cause serious injury and annoyance may continue to exist for may years.

The so-called "Thornwald's disease" appears to be nothing more than neglected adenoid hypertrophy.

Disappearance of the hypertrophy may be attended with an atrophic condition of the vault of the pharynx, the result of which is a pathological state detrimental to the patient and difficult to cure.

The above conditions may influence not only the locality in which they arise, but may have far-reaching and disastrous effect upon other organs. The ultimate prognosis as to the local condition, therefore, in cases of neglected adenoid hypertrophy, is unfavorable.

Infantile Pneumonia.

Most authorities agree that the pneumonia most frequently met with in young children and babies is the catarrhal variety, and the areas involved in this process necessary to make the baby a very sick one, are often so small that diagnosis by physical examination of the chest is sometimes very hard to make. It is in this case, however, that the pecularity of the cough gives us valuable aid in coming to a conclusion as to the presence of pneumonia. Where the baby gives one or several short coughs, followed immediately by a suppressed cry, with an expression of pain on the face, it is very suggestive, and if this sign is accompanied by dyspnœa, in which the nasal alæ play more or less violently and the temperature is elevated, we will rarely go astray in making a diagnosis of catarrhal pneumonia, irrespective of physical signs.—*Ex.*

MUSCULAR ASTHENOPIA AND ITS TREATMENT BY GRADUATED TENOTOMY.*

CHAS. HERMON THOMAS, M. D., PHILADELPHIA.

During the past decade a great advance has taken place in our knowledge of the anomalies of the ocular muscles. Until well within that time, the standard text-books on ophthalmology, so far as I am aware, recognized the so-called insufficiency of the internal recti only, as the cause of muscular asthenopia; affections of the remaining muscles being treated solely in their relations to diplopia and strabismus. It is now almost universally conceded that the opposing and vertical muscles are subject to like defects, with corresponding symptoms of equal or even greater importance. Recent editions of systematic treatises show that most writers now give to the whole range of muscular anomalies the prominence which their importance demands. Among these may be mentioned the latest edition the work of Noyes, which treats the subject elaborately, and also the works of de Schweinitz and of Norris and Oliver, both of which latter deal with it at considerable length. The increased interest and scope which the subject has acquired has resulted in the very general adoption of a new and systematic nomenclature—that originally proposed by Stevens. This improved terminology is employed by the authorities just named and is also introduced in the recent American editions of the works of Fuchs and Juler. As showing the increased importance accorded to the subject, it is worthy to be mentioned that at the meeting of the Pan-American Medical Congress, held in Washington within the past year, one day out of four was allotted by the Ophthalmic Section to the discussion of disorders of the ocular muscles.

The form of asthenopia under consideration results from disturbance in the normal use of the eyes as a pair—in effect acting as one single and not two separate organs—œil cyclopienne. The uncontrollable impulse to secure binocular vision, throws upon the extrinsic muscles of the eye a constant and delicate service during the continuous effort to maintain accurate adjustment in the fixation of objects viewed. Interference with the movements of the eyes by disturbance of the normal relations of their muscular components, calls for an excessive expenditure of nervo-muscular energy, to secure compensation and maintain the eyes in the proper position to secure single binocular vision. Exophoria—divergence defect—may demand the utmost exercise of the power of convergence, constantly applied; esophoria—convergence defect—on the contrary, that of an excess of abduction, involving the development of an unusual and abnormal innervation and muscular action. Such efforts may prove exhausting and are frequently the cause of disturbances which manifest themselves in a series of symptoms more or less marked and important.

The symptoms most frequently observed are, a sense of fatigue in the eyes, more or less constant and usually aggravated by definite use; objects viewed become indistinct and sometimes double, with occasional transient strabismus; headache; photophobia; dizziness; great discomfort while looking at moving objects, and when the patient is himself in rapid motion, as in looking out of a moving railway train; pain in using the eyes for definite fixation, which pain is frequently referred not to the eyes alone, but to the frontal, temporal or occipital regions, rarely to the vertex. Indeed, a large proportion of cases of headache, whatever the special variety, are symptomatic of eye-strain due to ocular defects and, many of them, to disturbances of the ocular muscles. Headache may supervene at once upon use of the eyes or it may be delayed.

The following conditions, alone or variously combined, are frequently present:—pain in the back; drowsiness in some, insomnia in others; a variety of reflex neuroses; mild blepherospasm, involving a few fibres only of the orbicularis; twitching of the eye-lids; palpitation of the heart; night terrors; nausea; indigestion; constipation and a host of other symptoms.

These symptoms and such as these, however, it will be seen, are often associated

* Read before the Medical Society of the State of Pennsylvania.

with accommodative asthenopia as well; excepting only the trasient diplopia or strabismus mentioned, and which is of infrequent occurrence.

On the whole, it may be said that the subjective symptoms of asthenopia as elicited in the consulting room, show almost no distinctive characteristics pointing to their especial origin, whether refractive or muscular; the same headaches and the same sense of eye-strain are complained of under both conditions. The test which has been given as differentiating the two disorders, namely, the use of one eye, the other being excluded from the act of vision for a time by covering it, has, in my experience, usually proven inefficacious.

Practically then, though the subjective symptoms alone are often inadequate to show the existence of muscular defect, objective investigation usually yields definite and uniform results, often indeed showing an exactness scarcely inferior to those obtainable in refractive determinations. Sometimes, but very rarely, the conditions found are inconstant or even erratic, and then great care is required in the estimation of their value.

As regards objective tests, the so-called cover test is the most readily applicable and is deserving of much confidence; it should not be omitted in any case. The diplopia tests such as vertical prisms, Maddox rod, etc., and the determination of abduction, adduction and sursumduction are indispensable in reaching a reliable conclusion.

It should be a fixed rule of practice to eliminate first the refractive and accommodative elements in any case under examination, by the proper glasses, leaving the muscular conditions to be dealt with at the last. Under these circumstances, it will be found occasionally, though not as frequently as could be wished, that the muscular anomalies vanish after correction of errors of refraction and accommodation; the final test as to which of these may be the active disturbing agent in any particular case, must frequently be the therapeutic test.

The following cases selected from my case books are presented as illustrative of the clinical history, treatment and its results in patients, the subjects of disorders of the ocular muscles:—

I.—T. H. L., mechanical engineer, aged 42, referred to me by Dr. W. H. H. Githens, June, 1891. Wearing high hyperopic correction combined with prism before each eye, 4 degrees, base in. Divergent squint, right eye deviating, except when attention is fixed. Diplopia except on great and tiresome effort, notwithstanding the prisms worm; much headache, confined mostly to the region of the brow. Reading and other definite and constant use of the eyes always at the expense of fatigue, which is only partially relieved by covering one eye; a page of ordinary size often overlaps one-half. Is particularly disturbed by sounds which are slight and not ordinarily noticed. Has multiple false images, monocular. Exophoria 14°. Operation, right exturnus, complete section, immediate result, Orthophoria. Two weeks later, Exophoria 8°, operation, complete, retrenched with suture, result, Orthophoria. One month later, Exophoria of 3°, reasserted. Exophoria in accommodation 20°.

Expresses much satisfaction in the comfort derived from the operation. Has no tendency to diplopia for distant, but somewhat for near vision. Has a new sense of solidity in objects reviewed; is conscious of definite binocular vision. There is also relief of the headache and of the abnormal sensitiveness to sounds. Finds that the use of eyes, as in accurate examinations of instruments and drawings, is now possible where it was not before. The false images, monocular, noted at the first visit, have almost entirely vanished.

Three years later, there is an Exophoria of 2°, Exophoria accommodation 26°, and an Ab. of 4°, and an Add. of 11°. Has passed the intervening time since the operation in occupations involving much use of the eyes, but in entire comfort.

II.—H. R. S., aged 48, master builder. A man of great physical strength and endurance; suffers severe pain localized in the eyes; complains particularly of the right eye feeling as "if it were drawn out by a cork-screw." This is accompanied by general nervousness and irritability with a prickling sensation over the whole body, after reading for a comparatively short time. Eyes feel dry and uncomfortable. All discomforts vanish to a great degree when away on vacation and the eyes are resting, except a severe headache which has been habitual and almost constant for years. Has high hyperopia, R 5, D. L 4, D.

Convergence defect; Es. 5°. Tenotomy right internus, result, Orthophoria. Four months later reported no headache since the operation and that relief occurred within 24 hours. All the symptoms before described have vanished. Patient highly appreciative of the change for the better which has taken place.

III.—H. W. P., retired merchant, aged 64; makes no complaint of pain or sense of strain, but only of some annoyance or inconvenience in the use of his eyes. He has a hyperopia of 1D, which corrected, gives him full vision in both eyes. He is able to fix distant and near objects with both eyes and at no time is there any manifest strabismus. He has a habit of opening and closing his eyes alternately every few seconds, during which act he elevates and corrugates the brow of the open eye excessively. This he does both in reading and in conversation, producing a very grotesque appearance, and, which being much remarked by his friends is, perhaps, the principal reason why he seeks advice.

A muscular test shows a divergence error, exophoria 20°, with a left hyperphoria of 2°. After wearing correcting prisms for a few days, the Ex. increased to 25 degrees and the Hy. vanished. An operation was then performed, a complete section of the right externus, resulting in a reduction of the Ex. to 13 degrees; and two days later a tenotomy was made on the right externus, not entirely complete, leaving an Ex. of 6 degrees. Six months later there remained an Ex. of 5 degrees. The habit of opening and closing his eyes alternately which was plainly an instinctive movement to avoid diplopia, had ceased with the operation and he expressed himself as entirely comfortable. His appearance is greatly improved. The small amount of exophoria remaining I deemed it conservative, under the circumstances, to leave uncorrected.

IV.—R. T. B. referred to me by Dr. Stubbs of Wilmington. Suffers from intense nervousness, extreme insomnia with mental depression, accompanied by suicidal fears. Close application to her work, (that of painting fine decorations on silk) causes distress of a grave character in the forehead near the eyes, sometimes running down the nose and extending to the face. Has had headache only recently. Uncontrollable winking at times, very troublesome, frowns habitually. Eyes not pained by use. Prickling sensation over the whole body, at all times, but mostly at night. Refraction normal, Es. 1°, Hy. 1°. Prescribed vertical prism correcting hyperphoria, which gave immediate relief, frowning ceased. Much irregularity of reaction of vertical and lateral muscles, but Es. of 10° proving very constant tenotomy of right internus was performed. Great improvement and abolition of all symptoms followed immediately. Three months later, orthophoria was established. Insomnia and nervous symptoms entirely abolished. Patient describing her condition said she was now entirely comfortable.

V.—W. J. D., aged 35, bookkeeper, referred to me by Dr. E. J. Nolan. Has high compound hyperopic astigmatism, for which he wears the correcting glasses, but complains of pain around the eyes with dull pains in the occiput. Symptoms aggravated by use of eyes for near work, interfering with regular duties. Has manifest Es. 12°-15°. Ordered prisms aggregating 10°, base out which were worn for a week with comfort. Es. advanced meantime to 22°. Tenotomy, right internus, complete section, result, Es. 4°. A week later 12° was manifested with marked recovery from convergence under cover test. A second operation, left internus, section almost complete; result, orthophoria when his sphero-cylinders are worn, though there is recovery from convergence, Es. 6°, when glasses are removed. Reports entire comfort and ability to use his eyes to an unlimited amount.

Considerable discussion has taken place as to the relative frequency of esophoria and exophoria, and different writers have asserted a marked preponderance on either side. A review of my cases for the last nine years shows that in the operative cases, as between esophoria and exophoria, these are almost exactly equally divided; and while there has been a certain variation on one side or the other from year to year, a close parallelism has been maintained in the main throughout the whole period. This examination also shows, as regards the refraction in both these forms of heterophoria, that hypermetropia predominated. The predominance of hypermetropia was more marked in the cases of esophoria than in those of exophoria, as the following figures show:

In esophoria the relative frequency of H. over M. was in the proportion of 3¾ to 1; in exophoria the relation of H. to M. was as 2½ to 1. Thus, while the most of the cases of heterophoria show hyperopic refraction—as is to be expected considering the greater frequency of this condition over myopia; when the static refraction is viewed in its relation to the accompanying heterophoria, we find that hypermetropia is usually accompanied by esophoria and myopia is most frequently associated with exophoria.

There is still to be found occasionally one who maintains the opinion that a complete tenotomy is required in every case of heterophoria calling for operation, on the assumption that no gain whatever is to be derived from partial severance of the tendon. My experience leads me to a directly opposite conclusion.

In my first paper on this subject, written six years ago*, I stated in effect that the fan-shaped expansions of the tendons of the recti at their insertion in the sclerotic are wider and thinner and their margins more elastic than is generally appreciated; and, that the elasticity of the margins is an influential factor in the production of a relaxation of tension in the tendon, graduated and definite in amount and permanent in character, permitting the effectual cental portions of the tendon to retract and form a new attachment to the globe further back. This I desire at this time especially to reaffirm and to add that graduated tenotomy is practicable and effective, only because of the elasticity of the margins of the tendons. No attempt is here made to distinguish between the tendon and its immediate covering derived from Tenon's capsule; for distinct as they are anatomically, they are one surgically, for the purposes of this operation, at least, and are to be treated as one.

It is true that occasionally a case is found in which no appreciable change in position occurs until complete severance has been accomplished, but such cases are altogether rare and exceptional. In the great majority of cases a gain graduated from 1 degree to 8 degrees may be made without complete severance. In those exceptional cases referred to, the tendon is thick and narrow at its insertion, and the elastic margins are either deficient or absent.

The technique of graduated tenotomy involves considerable difficulty and complication at times, and the performance of the operation is not to be looked upon as in any case a trivial procedure. It is an altogether more delicate and difficult operation than that for strabismus; and not less so indeed than any other operation done upon the eye-ball, not excepting that for cataract; but, when skillfully performed, it may be expected to yield definite and satisfactory results. It cannot be successfully undertaken without special instruments. Those devised by Dr. Stevens leave little to be desired. The ordinary strabismus instruments are altogether unsuitable by reason of their coarseness and clumsiness and should never be employed.

A study of nearly ten years faithfully pursued in all cases of asthenopia coming under my care has led me to the following conclusions:

Muscular asthenopia may present symptoms of all grades of importance, from the slightest to the most serious.

The muscular conditions in every case should, as a matter of routine, be as carefully investigated as are the media, eye-ground, refaction and amplitude of accommodation.

As in refractive, so in muscular asthenopia the gravity of the symptoms bears no constant relation to the amount of the physical defect. It is impossible to predict with any considerable degree of definiteness, the result of correction of either refractive or muscular error. As much and very much the same kind of relief is to be expected from the correction of the muscular anomalies as from the correction of errors of refraction and accommodation, as might be expected from the similarity in the symptoms which these conditions respectively cause.

During the earlier years of my study of these cases, I gave considerable attention to the graver neuroses—especially epilepsy—in connection with muscular anomalies; continuing the observation of a series of epileptic cases throughout a period of about five years. The results obtained in this series were altogether negative, not one recovering. With expectations of

*Graduated Tenotomy in the Treatment of Insufficiencies of the Ocular Muscles by C. H. Thomas, M. D. *Trans. Philadelphia County Medical Society*, March, 1888.

cure of epilepsy greatly abated, I nevertheless consider it proper to remove eye-strain of muscular origin in this affection as I would in any other condition; and for the additional sufficient reason that sound conservatism in the management of epilepsy calls for the removal of all possible sources of peripheral irritation.

TRANSLATIONS.

SALOPHEN AS AN ANTI-RHEUMATIC.*

DRS. B. CIULLINI AND A. VITI.

The following observations were made by the authors at the Clinic of Prof. Raimondi at Siena, and under his supervision. On the ground of these studies they consider Salophen an excellent remedial agent, both in acute and chronic rheumatism, its advantages over salol and salicylate of soda being that it is tasteless, not hygroscopic, and devoid of unfavorable after-effects.

CASE 1. S. M., female, aged 48, married; suffering from chronic articular rheumatism. Complains in the joints, especially of the right side, and also pains in the jaws; right knee slightly enlarged. January 26th, salophen 2.50 Gm., was administered. Slight diaphoresis was produced, but pains continued of the same intensity. No after effects. January 27th, Salophen 2.50 Gm., given, with slight relief of pains. January 28th, same dose; no change. January 29th, same dose; pain and swelling somewhat relieved; administration of remedy continued in same doses until February 4th, but as no improvement was observed, iodide of sodium was substituted which also failed to afford relief.

CASE 2. C. G., male, aged 59, had his first attack of acute articular rheumatism at the age of nine years, but enjoyed good health up to February 7th, 1893. Entered the Clinic February 13th, with tumefaction and pains in all the joints of the lower extremity, especially the tibio-tarsal, and also in the shoulder and elbow joints. On following day Salophen 3.0 Gm., divided in six doses, at intervals of two hours. The first dose was followed by a profuse perspiration which lasted six hours. No disturbance of the stomach or nervous system. Pain in the joints rapidly relieved; patient slept well. February 15th, Salophen 3.0 Gm.; no change. February 16, daily quantity increased to 4.0 Gm., divided in six doses. Profuse perspiration, pains slightly increased, no disturbance of stomach. February 17, remedy continued in same dose, and some improvement manifested, but pains reappeared during the night, especially in the tibio-tarsal articulation. During the following days under same treatment, pains disappeared entirely.

CASE 3. P. R., female, aged 45, married; subacute rheumatism, swelling and pains in various joints, especially the ankle and knee. February 17, salophen 3.0 Gm., in six doses. The first dose produced some diaphoresis, but no improvement. On the following day, dose increased to 4.0 Gm., and same quantity administered until February 20, when the remedy was replaced by sodium salicylate, which effected a cure in four days. A recurrence of pains ensued, and the patient was readmitted March 21st. Under administration of salophen for several days, followed by iodide potassium, complete relief was obtained.

CASE 4. S. S., aged 26; entered Clinic March 29, 1893, suffering from pains and swelling in various joints, knee, ankle, hip and wrist, of subacute character. Salophen was administered for seven days, in doses of 4.0 to 5.0 Gm. daily, reduced to 3.0 Gm., and produced rapid improvement, reducing the temperature and relieving the pains and swelling. Afterwards the cure was completed with iodide potassium.

CASE 5 A. C., aged 22, male; had suffered from repeated attacks of acute articular rheumatism. Admitted to the Clinic May 12th, with severe pains in the

* Translated for THE MEDICAL AND SURGICAL REPORTER.

arms and shoulders due to the subacute rheumatism. Salophen administered 4.0 Gm. in five doses, at intervals of three hours. Pains relieved, slight diaphoresis, no digestive or nervous disturbances. The dose was increased to 5.0 Gm. daily, and after five days employment salophen was replaced by salicylate of soda which acted more energetically and completed the cure.

CASE 6. M. V., aged 29, female; admitted to Clinic June 23d, with subacute articular rheumatism of the joints of the upper and lower extremities, especially the elbow, wrist and knee. Pains and swelling were present. Salophen 1.0 Gm. every three hours was administered, the first dose being followed by prolonged sweating, but no digestive disturbance. On next day, daily quantity of the remedy was increased to 6.0 Gm. and pains relieved. The remedy was continued until June 28th, when it was replaced by iodide of sodium which effected a rapid cure.

CASE 7. S. A., aged 47, male married; had suffered from subacute articular rheumatism, with swelling of affected joints. Salophen 1.0 Gm. every three hours, and continued for one week afforded some relief of pains. Salicylate of sodium then substituted, and employed for about one month with fairly good results. Later iodide of sodium and Piperazine administered, but no complete cure obtained.

CASE 8. M. E., aged 35, admitted September 23rd, acute articular rheumatism of all the joints; pains, swelling and impaired mobility being present especially in left ankle and knee joints. Temperature 38° to 39° C. Salophen given for six days, in 1.0 Gm. doses five times daily, and decided relief of pains and reduction of temperature manifested after two days' administration. Salicylate sodium then given for three days, and patient left Clinic October 25th., perfectly cured. In this case also, salophen showed itself preferable to salicylate of sodium, and acted as an efficient antipyretic and diaphoretic.

The author's conclusions are as follows:

Salophen is an active anti-rheumatic, better tolerated than salicylic acid and salicylate of soda and more innocuous than salol. In severe acute and chronic rheumatic affections it is somewhat less effective than the salicylates, and its chief indication is in the initial stages of acute arthritic and in mild or subacute cases. In obstinate or chronic cases it is advisable to follow its administration with that of iodide of potassium. The antipyretic action of salophen is not marked. In the intestinal canal it acts as an antifementative, and it destroys the reaction of indican in the urine. Doses as high as 5.0 to 6.0 Gm. *pro die* continued for several days are not attended with disturbances of any kind. —*Terapia Clinica,* April 4, 1894.

Effect of Climate on the Development of Children.

This is the title of a paper by Dr. T. C. Duncan in a late American Climates, which is of interest to climatologists generally. In the course of the paper he observes that physicians, who have made special observations on the difference between American and English children, report that the latter are more substantial, thickset, and less bright and active. Dr. Duncan attributes this difference to climate; England being more rainy and cloudy, and America more sunny and drier. American children are certainly more nervous from our drier atmosphere. Much of the apparent great composure of the English child is, however, an inherited as well as an acquired and cultivated sociological trait, not at all dependent upon the climate. Association has here a wonderful contagious effect. We all know that gesticulations, shrugging of the shoulders, and facial mobility during conversation, are supposed to be peculiarly Gallic accompaniments, and yet we have repeatedly seen reserved and taciturn Americans—a kind of a cross between the solemnity of our Puritan fathers and the stolidity of a blackfoot or of a Sioux—grimace, gesticulate, curve his back and hump his shoulders, wink and blink like a Marseillese the moment he acquired a fluent use of Spanish. Americans residing in England soon become more sedate, and American boys educated in England or France soon acquire more staid actions as well as a more staid form of expression in their speech, without losing any of their brightness. The moister air of England or of western Europe tends, however, to giving American children a more substantial body; they round out better and are not as restless as they are at home.—*National Popular Review.*

EDITORIAL.

USUAL PERIOD OF HEMORRHAGES IN PLACENTA PRÆVIA.

Having recently read that at a medical meeting the statement was made, "In central placenta prævia hemorrhage usually begins about the fifth month," and knowing it to be without any foundation in physiology or in facts, we have thought that quotations from some recognized authorities in obstetrics might assist in correcting the evil possibly arising from such publicly pronounced assertion.

Depaul, *Lecons de clinique obstétricale*, said that "the hemorrhage rarely occurs before the sixth month," and that "almost all hemorrhages from vicious insertion of the placenta, are produced in the last six weeks of pregnancy."

Charpentier states that the hemorrhages almost never occur before the sixth or seventh month.

"The losses show themselves at different periods. They rarely begin before the end of the sixth month, more often nearer the full period, and sometimes not until labor has actually commenced."—*Playfair.*

"Habitually the hemorrhage begins at the seventh or eighth month, and especially in the course of the ninth or tenth."—*Nægele and Grenser.*

"In lateral placenta prævia hemorrhages generally occur only after the thirty-second week, and in the central variety between the twenty-eighth and thirty-sixth week."—*Winckel.*

This author also states that there are cases in which the bleeding takes place in the first half of pregnancy, and others, not rare, in which, of both the lateral and central variety, the first hemorrhage appears only a few days before term, and in some instances as late as the beginning of labor.

Müller, in his monograph upon placenta prævia, the best of several upon this subject, observes that in the great majority of cases the bleeding first appears in the last weeks of pregnancy, especially in the last fifteen days.

Simpson's statistics, including 89 cases, furnish the following facts: First hemorrhage in 3 cases, before the sixth month; in 5, from 6 to 7 months; in 19, from 7 to 8; in 19, from 8 to 9; in 43, in the ninth month. Depaul's 70 cases give the following: In 1 case the hemorrhage occurred before the sixth month; in 7, from 6 to 7 months; in 12, from 7 to 8 months;

in 26, from 8 to 9 months, and in 24 at term, or near it.

So astonishing is the statement quoted as to when the hemorrhage usually occurs in central placenta prævia, we cannot believe any intelligent practitioner ever made it, but rather that the reporter has substituted fifth for seventh to eighth month.

ABSTRACTS.

THE ICE BAG AS A CARDIAC STIMULANT.

A writer in *La Medicine moderne* is quoted in *La Province medicale* for April 7, as saying that the application of an ice bag over the heart, according to Dr. Jullien, is a powerful therapeutic measure. It seems that in 1887 M. Jullien read in the *Gazzette delle cliniche* an essay on this subject by Dr. Silva, and was struck with the author's conclusions. Experimentation upon animals had shown the possibility of raising the blood pressure rapidly from a hundred and twenty millimeters to a hundred and seventy and even a hundred and ninety, and of diminishing the frequency of the pulsations considerably; and these results had been confirmed clinically. M. Jullien was not slow to verify these observations for himself. One day he was called to take charge of a patient with typhoid fever. He advised treatment by means of cold baths, and transferred the patient, a large and strong young girl, to the care of a colleague. Soon afterward, however, his colleague's illness rendered it necessary for him to take charge of the case again. It was a grave one and the febrile phenomena were intense. The elevation of temperature proved rebellious to the use of cold water. Soon there was a typical picture of the ataxoadynamic form of the disease. The patient had lost consciousness entirely and lay on the bed entirely uncovered in a tetanic attitude varied only by the certain spasms of the head. The temperature remained all the time above 104°; the pulse had reached sucessfully 120, 140 and 160. Under these circumstances M. Jullien fancied that the application of ice over the heart might constitute a last resort, and he made bold to carry it out. He admits that it was not without timidity that he placed the rubber bag on the region which scarcely showed the tumultuous and enfeebled beats of the exhausted heart. He watched the pulse closely, ready to stop the attempt at first signal of danger. But in less than fifteen minutes he saw the number of the pulsations diminish and their amplitude increase; in a short time the almost imperceptible undulations of the artery gave place to more decided elevations. Whenever he removed the refrigerant the alarming symptoms returned immediately, so that after many trials he concluded to leave the ice bag in place for several days. After that the temperature yielded, the cerebral phenomena disappeared, and the patient was out of danger. He is convinced that she owed her safety to the decisive measure which he had adopted. In another case also he accomplished a result equally remarkable by this means. In conclusion, he remarks that the beneficial effects show themselves in from fifteen to twenty minutes from the beginning of the application, and reach their maximum at the end of an hour. It is true, he says that they are evanescent; disappearing rapidly when the application is suspended, but there is no danger in prolonging it as long as the general condition remains precarious. In some cases, under its action, the height of the pulsation has been observed to be tripled, which means a pulse ampler, fuller, and more tense, with the subsidence of dicrotism, intermittence, and irregularity, and with a longer duration of the diastode. An interesting fact noted is that the effects of alcohol and those of atropine on the circulation are in a measure neutralized by the ice bag. This, says the author, is not astonishing, since alcohol has the property of lowering the blood pressure by paralyzing the vasomoter nerves, and atropine increases the frequency of the pulse by parlyzing the pneumo-gastric nerve. This antagonism, he suggests, may possibly be serviceable in some cases of poisoning.—*N. Y. Med. Journ.*

NARCOMANIA.

Experts and noted writers agree that this term describes more accurately the condition of many inebriates, than dipsomania. The latter indicates a thirst mania, which is very rarely seen, and of short duration, while narcomania is a mania for relief, or the intense desire for the anesthetic effects of alcohol, opium or any drug which will quiet the physical or psychical sufferings of the organism, and is common to most cases of alcoholism. An inebriate who has become powerless to control this alcoholic impulse, and who gives way to it continuously, or at intervals, is a diseased man requiring medical recognition and care.

Such men are what may be termed defectives, and in most cases are of bad judgment, weak, erratic, changeable feelings and morbid enthusiasts. Recently the prominence which a few men of this class have taken in the affairs of the country, bring up the question of their mental condition, and suggest a new study and change in public sentiment. A practical illustration is that of a business man, at the head of a large industry, who drinks to great excess at intervals, and whose bad judgment and insane-like reasoning has on several occasions caused great suffering to those whom he employs, and the community in which he lives. Lower down, a man who drinks at intervals has attacks of delusional mania and causes distress and suffering to those about him; or commits crime which perils the interests of the community.

Another class growing more prominent, are so-called reformed inebriates, who after years of excessive use of spirits, seemingly stop drinking, and become wild agitators, and sensational leaders of impractical theories. They call themselves pioneers, socialists, and are active to change and disquiet the existing order of events. They are prominent in all new schemes for money, power and popularity; and after an uncertain period relapse, and become wilder and more irregular. They are becoming prominent in every community, as supporters or opponents of every possible good or bad theory, quackery, delusion, socialism, anarchism, and are so-called reformers of every degree. As advocates of "gold cures," they have tried the treatment and then enter upon the business of curing others. Becoming officers of branch cures, they urge the most extravagant expectations in pecuniary returns, and possibilities of curing others. Later the institution is bankrupt, and they relapse and disappear. The head centers who provide the secret remedies, wisely receive all pay in advance, and never trust, while the credulous stockholders and supporters of these branch cures, trust to the pretensions of these reformed officers.

Many of the extreme reformers, who create a large following for a time, then disappear under a cloud, are of this class of narcomanics. Sometimes in medical circles these cases appear, urging some very startling innovations in remedies and treatment, or claiming some discoveries which threaten to change all existing order of events. Not unfrequently they pose as enthusiastic advocates of some half way proprietary medicines.

The general public overlook the fact that such cases are "border briers," and not unfrequently pass over into the realm of insanity, both acting and reasoning like insane men. In the interval they may pass unobserved in may circles, and be credited as of sound mind. But when they commit crime and become objects of study, a new chain of symptoms appears pointing out states of degeneration not noticed before. Physicians should enter upon this neglected field of psychical and obscure mental symptoms, and be able to make diagnoses of cases, that are seldom recognized until they fall into the hands of specialists. Narcomania is only one of many of these obscure degenerative mental disorders, which may go so far, then stop, or continue to some pronounced phase of insanity. An early diagnosis of a paranoiac and defective brain, and appropriate care and advice, would save most disastrous consequences later. So-called habits, conduct and methods of reasoning, should be the subjects of medical study as much as the heart's action, the temperature and reflex of the body.

The narcomaniac is diseased and requires medical care and treatment, and the general practitioner is in a position to study and understand these cases more clearly than the specialists.—*Jour. Am. Med. Ass.*

AN EASY METHOD OF BATHING IN TYPHOID FEVER.

Every new medical text-book and periodical accumulates statistics testifying to the brilliant results following the use of cold baths in typhoid fever. The hospitals in which this method is chiefly carried on are almost, without exception, showing a higher percentage of recoveries than ever before under any other plan of treatment.

Why is it, then, that this method is not universally adopted and carried out in private practice? The answer is simple.

Easy as it is in a hospital with an abundance of skilled assistance, there is no method of treatment in use so difficult to carry out properly as tubbing in typhoid fever in private families.

As the family bath-room is generally out of the question on account of its inconvenient location, and use by others of the household, it becomes necessary to buy a large portable bath-tub.

Even in cases where there are two trained nurses it is necessary to call in the clumsy assistance of some members of the family to help in the lifting of the patient to and from the tub, and this is a strain on them, and not unattended with risk to the one who is sick.

There is undoubtedly still a widespread opposition among the laity, both educated and uneducated, to the use of "cold baths" in fever. A young physician must have a very strong hold on the family, and enjoy their most complete confidence, to take the risk of the responsibility, if the disease takes a bad turn later from any accidental complications, and even older men will sometimes hesitate.

A physician of high standing and extensive practice in the city recently said to me, "I do not find that tubbing is practicable in private families, much as I would like to make use of it. I have to content myself with sponging and packs, and have had some success with constant use of an ice-coil over the abdomen as a substitute. If the ice-coil acts so well in lesions of the peritoneal coat of the intestines, why should it not have a similar result in lesions of the mucous coat?"

But all these three methods, sponging, wet pack, or ice-coil, while they add to the comfort of the patient, do not cause very decided or long continued lowering of the temperature.

Again, one who has had bad results from necessary changing of the position of a patient in an advanced stage of typhoid to examine the back of the chest, or something equally simple, causing disagreeable heart symptoms, will rather dread the process of lifting a patient out of his bed for any reason whatever, especially if the patient is large and the bed a double one.

The following method, which I once saw used in a hospital in Buffalo, commends itself as a simple solution of the whole problem. I have never seen it published in any medical journal or work, and am sure that it has not often been tried.

It is a very easy thing to slip a rubber blanket under the patient, and raise the two sides and the ends at the foot and head of the bed, nine or ten inches, by a row of pillows, bolsters, sand-bags, or simple boards.

The rubber blanket ought to be of double thickness, as large as can be purchased, and special care must be given to the arranging of the corners. When this is done you have the patient at the bottom of an impromptu bath-tub, into which you can pour water at any desired temperature, and in sufficient quantity to partially or entirely cover his body.

Only two inches of water would be enough to give a cool sponge-bath ten times as efficacious as the gingerly sponging possible under ordinary circumstances, and if the sides and corners are firmly fixed you can easily make this tub hold all the water you desire. The water may be run from the nearest faucet by a rubber tube. I have found it a simpler and equally successful method to carry it in pails and pour it over the patient, starting with tepid and gradually cooling it down to the desired temperature.

The neatest method I have found by experiment is to use a large "watering-pot" with a sprinkler, such as is used for watering plants. This is a method which will not commend itself to those who dislike humble and commonplace methods to accomplish something that more complicated and more impressive methods might do.

I believe this kind of a bath will always be grateful to the patient, and if it is found necessary to use water at a decidedly low temperature, would give rise to less shock than a sudden plunge into a tub filled with very cold water. The effect on the temperature is the same as it would be under the other method with a stationary tub.

The water can be removed, without spilling a drop on the bed, by siphoning with a rubber tube, or dipping with a small pitcher or cup, or sponging. Then the blanket can be dried and left in place, covered by a clean sheet, or better yet, removed and dried in the sun.

All this needs a little care, for it would be a very serious and troublesome accident to soak the patient's bed-clothing and mattress, but the difficulty and risk to the patient cannot be compared with that attending the use of the ordinary tub. And best of all, in those cases where the family or friends must do the work, and the employment of trained nurses is impossible on account of expense, this method can always be successfully used when tubbing would be out of the question.

I have not found one single objection to the employment of the method in private cases, and cannot see why it could not be used in hospitals.—*Med. Rec.*

Music as a Healing Power.

The idea that music possesses an actual healing power is about to be tested in London. The Guild of St. Cecilia is about to build or hire a large hall, in which musicians, especially trained to sing and play the very soft music which alone should be administered to those whose nerves are weakened by illness, shall perform by day and night. Telephones will connect this composite and continuous music-room with certain wards of London hospitals. Records and data of conditions and effects are to be kept, and conclusions arrived at. —*Medical Record.*

Puerperal Convulsions and True Epilepsy.

Paquy (*British Medical Journal*) recently read notes at a meeting of a society on a patient who was frequently attacked with epileptic fits. She became pregnant, and at a delivery had 119 fits. The temperature rose to over 102°. The diagnosis between puerperal eclampsia and epilepsy depends on the history and on the absence of albuminuria in simple epilepsy. Charpentier observed a similar case. An epileptic patient had convulsions during her first labor, became pregnant again, and died after a succession of fits during the fourth month. He agrees with Paquy as to albuminuria as a diagnostic factor.

Ocular Headaches.

Dr. F. D. Green (*The Refractionist*) concludes an article on headache as follows:

1. Many cases of headache are due to ametropia.
2. Many cases are due to heterophoria.
3. Never pronounce a case as due to ocular strain until the nose is examined.
4. Inquire into the condition of the stomach.
5. In females inquire concerning the condition of the genitals and whether there is constipation.
6. Migrane may be due to ametropia or heterohhoria, but frequently is not.

The Cold Bath the Best Antipyretic.

Numerous experiments have shown beyond room for doubt that heat production of thermogenesie chiefly takes place in the muscles. Heat production is of course most active during exercise, but is continually in progress under the control of the thermic centers of the brain and spinal cord. The fact that an application of cold to the surface reflexly induces an increased thermogenesis has been used as an argument against the cold bath as an antipyretic, but MacAlister's experiments show clearly that the prolonged application of cold to the tissues inhibits heat production by cooling the muscles, while it at the same time abstracts heat.—*Modern Medicine.*

SOCIETY REPORTS.

PHILADELPHIA ACADEMY OF SURGERY.

Meeting June 4, 1894.

Richard H. Harte, M. D., Surgeon to the Pennsylvania and Episcopal Hospitals, read a paper on

A CASE OF PYÆMIA DUE TO APPENDICITIS.

The history of the case I wish to present to you this evening is as follows: A. C., aged twenty-five years, a weaver by occupation, was admitted to the medical wards of the Episcopal Hospital, May 9, 1894, at the request of his medical attendant, Dr. Ferguson, supposing the man to be suffering from abscess of the liver.

On admission the following facts were elicited, which I have copied from the Resident's meagre notes: *Family history*, negative. *Previous history*: Enjoyed good health, although not especially robust; about three years ago recalls having a short illness ushered in by a chill, the prominent symptoms of which were sharp cramplike pains referred to the lower third of the abdomen; was confined to bed for a week. (This was undoubtedly an attack of appendicitis.) *Present attack*: States that he was feeling perfectly well up to about two weeks ago, when he was awakened with sharp pains in the right iliac fossa, and in the course of the morning they were followed by a pronounced chill, succeeded by sweating; through the day he felt nauseated, and in the evening vomited.

During the interval of two weeks from the time of his first attack until his admission into the hospital, he had always once in the twenty-four hours, and sometimes oftener, a decided chill followed by profuse sweating; pain, referred in the right iliac, umbilical and hypochondriac regions was almost continuous; the bowels were watery, and moved daily; the patient was confined to bed and growing weaker.

After his admission into the medical wards all his symptoms were referred to the region of the liver, over which there was distinct tenderness. The daily chill and high temperature (106° F.) naturally led my colleague, Dr Morris on the medical side, to suspect abscess of the liver, and he transferred the case to the surgical wards for operation.

On the day after his transfer to the surgical wards I found the case very much as above stated, the right hypochondriac region being tender on pressure, liver area increased. On examining the case in the ward before operation I exposed but a small portion of the abdomen and noticed a distinct eruption which I supposed was due to the vigorous use of a scrubbing brush. The case was then taken to the operating-room and etherized, and on a more careful examination of the abdomen under an anæsthetic, I found the eruption, which I had first supposed was due to the bichloride and friction, to be pretty generally distributed over the entire trunk, and in appearance was not unlike the eruption of typhus fever, or, in other words, a distinctly morbilliform eruption. The history at that time in my possession was rather negative, and I decided not to operate until more definite data could be obtained. On the following day I saw the physician under whose care he had been and with my colleagues, Drs. Deaver, Neilson, and Morris decided to make an exploratory incision over the region of the liver. The patient was etherized, and an incision corresponding to the right semi-lunar line gave a free opportunity to explore the surface of the liver, which appeared normal. An exploration with an aspirating needle failed to reveal any purulent collections. The region of the appendix was explored through the abdominal wound, suspecting that possibly it might be the seat of the trouble; but with the hand carried down over the liver to the right iliac fossa, no evidence of trouble was apparent.

After the operation the chills seemed to be less severe, not being so frequent as before, and the temperature not rising high. The external wound closed quickly, and no symptoms relative to the operation were manifest. The next chill was four

days after the operation, and did not rise nearly to within two degrees of the height of the previous one. The next chill did not appear until the fifth day, although the patient was gradually growing weaker, and died on the tenth day after the operation. After the second chill he began to expectorate bloody mucus, sometimes a cupful of blood being expectorated during the twenty-four hours.

A post-mortem examination revealed the liver slightly enlarged and filled with a large number of metastatic abscesses, the principal pus collection and largest abscess being in the left lobe. The appendix was entirely destroyed, and its position occupied by a small pus cavity holding about three drachms of pus. The cæcum for several inches beyond its attachment to the appendix was gangrenous. There were some septic deposits in the lungs although no distinct infarcts were to be found. The reason I ascribed for the liver being affected, which is usually a secondary affection coming under the general circulation, is that the materies morbi coming from the appendix immediately entered the portal circulation—superior mesenteric vein—and consequently the first deposit would naturally be found in the liver.

The post-mortem here distinctly revealed a case of infection arising from the appendix. One peculiar feature in the case was the eruption, which was more or less misleading, although eruptions in suppurative fever, or pyæmia have long been recognized, and are spoken of by Braidwood in his exhaustive treatise on that disease.

My object in briefly reporting this case to-night, is that I think it of no little interest (without wishing to go into the subject of pyæmia, which is so familiar to all the Fellows of the Society), throwing as it does more light upon the much mooted subject of appendicitis, and again, adding its weight to the testimony that the above mentioned disease is strictly a surgical affection rather than a medical one; for I feel certain that had the true condition of affairs been recognized at the onset of the attack, the ultimate termination might might have been different.

DISCUSSION.

DR. WILLIAM J. TAYLOR: Some ten years ago I made a post-mortem examination for Dr. William Moss, of Chestnut Hill. At that time we did not know very much about inflammation of the appendix. There was a long-standing condition which was supposed to be an ulcerated condition of the bowel. It was undoubtedly due to inflammation around the appendix. There was also pyæmic abcesses throughout the liver. The patient, a boy fourteen years of age, had died of general pyæmia due to infection from his inflammatory condition of the appendix.

DR. T. S. K. MORTON: I have never met with pyæmia where abscess about the appendix was found, but I call a number of instances in literature where pylephlebitis had extended from the abscess cavity directly to the liver. I have seen one or two cases where intense jaundice accompanied this condition. One of these cases was in the practice of Dr. Steinbach. Here it was quite evident that the infection about the appendix had travelled by the lymphatic or venous route to the liver.

THE PRESIDENT: Pyæmia associated with appendicitis must be a rare condition. I do not recall having seen it. I take it that those cases in which there is distinct evidence of involvement of the liver are essentially fatal.

DR. L. W. STEINBACK: The case referred to was one of appendicitis in a young man. I saw him for the first time on the fifth or sixth day of the disease. Slight jaundice was present at the time of operation, but increased rapidly after the operation. The patient lived a week or ten days after the operation.

C. B. Penrose, M. D., contributes an article on the

USE OF THE ABDOMINAL DRAINAGE-TUBE DETERMINED BY BACTERIOLOGICAL EXAMINATION.

The subject of drainage in abdominal surgery is one about which there is still great difference of opinion, though this difference is much less than it was only a few years ago. Some operators never used drainage at all after any operations, and yet obtained exceedingly good results; while others obtained equal results, and their statistics showed that they employed drainage in a proportion of their cases, which varied, according to the individual taste of the operator, from 5 or 10 per cent. to 75 per cent.

The general advice given by the advocates of draniage was "when in doubt,

drain." It was this element of doubt which caused the diversity of practice. The doubting operators drained the most. Everything which increases our knowledge in regard to the facts which determine drainage dimishes our doubts and brings about more uniformity of practice.

We drain the abdomen for two reasons —for hemorrhage and for septic material. As the experience of the operator increases and his skill in enucleating tumors becomes greater he has less hemorrhage and, other things being equal, he drains less. Our methods of controlling hemorrhage in abdominal operations are better than they were a few years ago, the Trendelenburg posture enabling us to check bleeding from small vessels in the bottom of the pelvis, which before the introduction of this position required drainage. The operator who enucleates pelvic tumors with two fingers and closes the abdomen without seeing what he has done will necessarily have much more doubt in regard to hemorrhage and will use the drainage tube much more frequently than the operator who inspects the field of enucleation before closing the abdomen.

The second reason for drainage is the septic character of the material which escapes or is retained in the abdomen. Knowledge in regard to this fact is of great value in deciding about drainage in any case.

During the past winter, at the University Hospital, an immediate bacteriological examination has been made of the contents of every tubal or ovarian tumor which was ruptured during removal. And the report of the pathologist in regard to the septic or the aseptic character of the contents has determined my decision in ragard to the use of the drainage-tube.

I, unfortunately, have no record of the total number of cases in which such examinations have been made; but the results have been exceedingly satisfactory, for out of a series of 46 celiotomies, in which drainage was used but three or four times for hemorrhage, and only once because the microscope showed the material which escaped into the abdomen to be septic, there has been no case of peritonitis or sepsis.

The tubal contents in most cases of salpingitis are sterile. Shauta (*Archiv für Gynecologie*, 1893, No. 44) reports 192 cases of salpingitis, in 144 of which the contents of the tubes were sterile, in 33 there were gonococci, and in 15 streptococci or staphylococci.

Before I began to use this method of bacteriological examination I inserted a drainage-tube in every case of tubal and ovarian abscess where the contents escaped into the peritoneum. Now I neither irrigate nor use the draidage-tube unless the microscope shows these contents to be septic. The presence of gonococci in small numbers does not necessitate drainage. Recently the value of this bacteriological examination was illustrated by two cases operated on consecutively. Each woman had a tubo-ovarian abscess, caused by sepsis or labor. In each case the abscess was ruptured during removal, and the pelvis filled with pus. In the first the pus was found to be sterile, and I closed the abdomen without irrigation or drainage. In the second one pus contained streptococci and staphylococci and coli commune. Consequently, the pelvis was thoroughly washed out and drained.

Both women recovered without peritonitis or sepsis, though the convalescence of the first was very much easier than that of the second.

The examinations have been made for me by Dr. Beyea. Cover-glass preparations of the material to be examined are made and are fixed in the flame of an alcohol lamp, and stained with carbol fuchsin. The microscopic examination is made with a Leitz 1/12 immersion lens.

The examination is quickly and easily made, and I think that no operating room is completely equipped without facilities for such bacteriological examinations. They furnish us with scientific data from which we can determine the propriety of an important surgical procedure, which otherwise depends upon the whim or prejudice of the operator.

DISCUSSION.

DR. J. EWING MEARS: I think Dr. Penrose has made a very valuable contribution to the literature of this subject. I am reminded of some work of a similar character which has been done by Dr. L. McLean Tiffany, of Baltimore. At the recent meeting of the American Surgical Association, in the discussion on empyema, he stated it was his custom to submit the fluids removed from the chest cavity to bacteriological examination, and the ques-

tion of the kind of operation and washing out the cavity was determined by the result of this examination. The value of this work cannot be over-estimated. It enables us to make our diagnosis positive, and determines the character of treatment to be employed.

Dr. Richard H. Harte: I believe with Dr. Penrose that no operating room is complete without a suitable bacteriological plant. At the Pennsylvania Hospital, with the assistance of the pathologist and one of the residents, I have been trying to do some work of this character, and have derived a great deal of assistance from it. I notice in a number of operating rooms in new hospitals that a bacteriological room is also provided. A great deal of information as to the necessity for drainage can be obtained in this way.

CONVULSIONS AND RICKETS IN YOUNG CHILDREN.

A late Review of Insanity and Nervous Diseases contains an interesting translation by Dr. Kaumheimer, on the mutual relation of tetany, rickets, and laryngeal spasm or spasm of the glottis in childhood, something which deals with a subject that is not fully appreciated or understood until one is brought in contact with a case. Of the many works on diseases of children that are used as text-books, none contain as lucid or as graphic a description of this condition as the really classic work of West.

In these days of bottle-raised infants the disorders that arise from malnutrition, and which often drift into tetany and rickets from the latter cause, are more numerous than one might at first imagine. Kassowitz, in the above translated paper, observes that laryngeal spasm is found almost exclusively in children who present unequivocal symptoms of active rickets, and he finds it to be more prevalent in the winter and spring months. In this connection Kassowitz calls attention to the nervous disturbance found in rickety children, such as insomnia, localized sweating of the head, starting at slight sounds, expiratory apnea and spasm of the glottis, and generalized convulsions. The former symptoms precede the convulsions in rickets, and the family physician can not too urgently insist upon the need of a better general hygiene—which includes the very important and the all-powerful question of a proper diet—upon noticing any or being told of the presence of the premonitory symptoms that warn us of the danger of a general convulsion from this cause. In some children there is at the outset an hyperexcitability of the facial nerves, while in others we have observed a peculiar dry cough, such as ushers in the incipiency of Potts' disease of the spine.

In a general way a child is well under way in the disease before the parents consides its condition sufficiently important to call in a physician. In most cases the physician is really not called until violent convulsions have occurred. The physician may reach the patient during a convulsion, and it is then that he must bear in mind the connections that exist between laryngeal spasm and rickets and the condition he is called to attend. The parents and neighbors will have probably concluded that it is a case of worms, but in a case of convulsions due to rickets we must at once assure ourselves as to their real cause, as an entirely different plan of treatment must be pursued. Kassowitz places his main dependence on phosphorus. Cod-liver oil —not the emulsions, but the pure oil— administered both internally and externally, has proved a valuable remedy in our hands. West advises cod-liver oil and iron, careful dieting, and change of air. During the convulsion, cold—ice if procurable—applied to the head, and chloral with bromides are the appropriate remedies; at the same time the bowels should be freed of any irritation by enemata. As before said, however, the parents and the physician should at once look into the child's condition upon the first appearance of any of the premonitory symptoms that denote that the child is drifting into rickets, and not wait for a convulsion. The physician called when a child is in convulsions should well differentiate between the various causes that tend to produce convulsions, and he should be on the lookout for rickets.—*Nat'l Popular Review.*

CURRENT LITERATURE REVIEWED.

IN CHARGE OF ELLISTON J. MORRIS, M. D., AND SAMUEL M. WILSON, M. D.

ARCHIVES OF PEDIATRICS

for July. Dr. J. Henry Fruitnight writes of

Infantile Scurvy, Especially its Differential Diagnosis.

This trouble is increasing, especially among the more wealthy class, because the children are less frequently breast-fed than they are among the poor, and because it is becoming a custom to use prepared baby foods, sterilized milk, etc. The poor on the other hand have not money to waste on these preparations, and if a baby is not breast-fed it is given such a variety of tablefood that scurvy, at least, is not apt to develop.

Mr. Babes (of New York) investigating the histology of the disease, finds a lessening of the number of red corpuscles and a decided leucocytosis.

To show the symptomatology of the disease some clinical records are given. The first of these describes a child puny at birth, who was taken from the breast at the end of the first month, on account of the mother being phthisical. The child showed no evidence of this disease.

The child was fed on a "baby food" and failing in health was transferred to sterilized milk, but seemed constantly hungry, was given one artificial food after another and failed to improve. The mother noticed the child commencing to shrink from her daily bath, then that the left ankle was becoming tender, then that the right arm gave pain when moved. The gums now became swollen and dark, and then began to bleed when touched. Acute articular rheumatism and difficult dentition were diagnosed and treated without benefit.

When seen by the author there was a tense fusiform swelling at the left ankle joint, another at the knee, both very tender. Temperature was 100°, pulse feeble and rapid, gums dusky purple with unhealthy granulation tissue, cheeks and tongue ulcerated, ecchymotic spots over the limbs, abdomen, and back, and, over the right eye, a spot giving the appearance of a black eye. Blood was passed in the stools, but there was no diarrhœa.

Under treatment by Pasteurized milk prepared Freeman's method, and by orange juice ʒi every two or three hours and one and one half grains of the citrate of ammonium and iron every four hours, the child made a perfect recovery. The legs improved first, then the mouth, finally the ecchymoses were absorbed.

The second case had the typical appearance and the history of rickets. When seen the temperature was 103°, the thighs just above the knees were swollen and tender, unmovably extended and any attempt to move them caused an increase in the cries of pain.

A supparating haematoma due to subperiosteal effusion, was found posteriorly and above the right knee and burst the next day. Below the knee was an extensive lymphangitis. The gums were spongy, dark red, ecchymotic.

The child was given good cow's milk diluted with one-third oatmeal water, orange and lemon juice, twenty drops every two hours, and scraped apple pulp.

Citrate of potash 5 grains t. i. d. and citrate of iron and quinine 1½ grains, with dilute nitro-muriatic acid were given and rapid improvement resulted.

Another case resembled Pott's disease in many respects, showed weakness in sitting up and seemed to double up as though the spine were diseased and causing partial paralysis and she showed pain on being moved. This patient improved very promptly on being put on scorlutic treatment.

(TO BE CONTINUED.)

Dr. A. Leibert contributes an article on

The Filteration of Milk

which he read before the American Pediatric Society.

Mentioning the fact that milk contains many impurities, hair, dirt, etc., which are undesirable, and which sterilization would not remove, he had tried filtering. The filter chosen was absorbent cotton, and it was, as had been expected, quite effective, but to his surprise he found that the useful constituents cream, etc., were not removed at all, and not only this, but also that the number of bacteria was reduced very greatly.

A careful examination showed that if the cotton were first moistened, the number of bacteria would be reduced to about one-eighth of the number originally present.

To confirm these observations Dr. Otto Kiliam was requested to go over the same subject and he had similar results.

The experiments made are given at length and were quite conclusive.

Dr. J. L. Smith concludes his article on

The Alimentations of Young Children

giving the chemical changes taking place in lactose in milk in normal digestion, in alcoholic fermentation, as in flatulent dyspepsia and in butyric fermentation of putrefaction.

He describes the sanitary method of milking a cow and shows several points to be observed in sterilizing milk, and the injury resulting to the milk and to the infant using it if these points are not observed.

Finally he mentions the successful use in a foundling asylum of: six or eight drops of

essence of pepsin or elixir of digestive ferments, followed by one ounce each of dexterineized barley gruel and Pasteurized upper part of milk, every two hours for infants under two months of age. Every hour they are given ten drops of "Panopeptone." The upper part of milk means the upper third or half of milk that has stood for a few hours in a can.

Dr. S. A. Sutherland reports a case of

Cerebellar Tumor; Subsidence of Symptoms; Complete Recovery.

One week after a fall from a table, the patient, a boy 3½ years old, complained of headache, the pain beginning in the occiput and radiating to the vertex. The severity and frequency of attacks increased and finally violent screaming at night began. During a severe attack the head was stiffly retracted.

Double optic neuritis was found, staggering gait, and dragging of the limbs in walking, kneejerks markedly exaggerated, and in trying to grasp an object the fingers often became stiff.

An operation was not thought advisable. During the next two months the weakness increased, vomiting appeared, free epistaxis, and complete loss of power of walking and of balancing. Then improvement set in and in one year he was in almost perfect health.

The treatment was cod liver oil and iodide of potash and afterward iodide of iron, but the author thinks that the cure was a spontaneous one, due to encapsulation of a tubercular neoplasm.

This number also contains a description by Dr. Edward Pisko of a case of "Scleroderma," and an Eulogy of Drs. John M. Keating and Charles Warrington Earle, by Dr. F. Forchheimer.

JOURNAL OF GENITO-URINARY AND CUTANEOUS DISEASES.

for July. Dr. Alexander W. Stein discusses

Exfoliation of the Mucous and Sub Mucous Coat of the Bladder Preceded by Renal and Vesical Calculus.

When cases of desquamation of the urethra are mentioned they are classed under such titles as "Membranous Urethritis," etc., but the author has seen cases where there was no apparent inflammation—where the urine was normal, and which showed no symptoms of general disturbance and yet where casts of the uretha formed, projected as dry masses, and could be withdrawn without much discomfort. Both of these patients had used strong astringent injections for gonorrhœa several months before.

A few writers casually mention a croupous or diphtheritic cystitis, but that the whole mucous membrane of the bladder could exfoliate has been denied. The author has found many records of the entire mucous coat being cast off and in some instances portions of the muscular and even a part of the peritoneal covering.

The epithelial cells of the bladder have greater vitality than similar cells elsewhere, yet we can easily understand that any mucous surface severely irritated, as by the use of strong urethral injections or by the presence of ammoniacal urine might exfoliate.

It is not unusual to find, at autopsies, submucous ecchymoses in the bladder, and the loose attachment of the mucous and deeper coats explains the frequency. A slough would readily follow an ecchymosis of any great extent, and this is favored by the poor blood supply directly in the mucous coat, most of the vessels lying in the muscular layer.

"Retention of urine" is generally given as the cause of most trouble of this description, and it is more than probable that this acted by compression of the blood vessels, both venous, plexus and arteries being mainly in the region of the bas fond. In fifty cases tabulated, forty-five were women and the trouble said to be due in these to either a retroverted gravid uterus, or to the pressure of the child's head. The author then gives the history of a patient of his who after passing several phosphatic calculi had litholopaxy performed, and although greatly relieved, began some time later to pass shreds by the urethra. Some of these were quite large, and on examination they proved to be the altered mucous and submucous coats of the bladder.

The case had been complicated by what was probably pyonephrosis and after passing out of the author's observation was reported to have died of uræmia.

Dr. Eugene Fuller continues his article on

Chronic Seminal Vesiculitis

by giving a number of cases treated by him. Some of these cases were purely gonorrhœal, some purely tubercular, and some probably due to gonorrhœa in a tubercular patient, and another seemed due to excessive coitus.

As soon as a case was found to be purely tubercular the local treatment was stopped. In a mixed case great care was taken to avoid increasing the tubercular element by too great manipulation, and of course while care was taken in a purely gonorrhœal case to avoid increasing the irritation still the local treatment was the main reliance.

Concluding the article Dr. Fuller impresses the fact that by no means all chronic gonorrhœas are due to seminal vesiculitis or will be benefitted by treating those organs, and that tubercular vesiculitis is so common that it is necessary to use great care even in the rectal examination, or many cases will only be aggravated.

He goes on to state that the discharge generally ceases before the cure is complete, the treatment usually varies from a month to possibly a year, and should be applied once in five or seven days, or, if it excites inflammation, a longer period may elapse before its repetition.

In the report of the eighth annual meeting of the American Association of Genito-Urinary Surgeons there is given the discussion of Dr. Chismore's paper on a modification of Bigelow's operation for calculus.

The enormous amount of cocaine the author uses excited much interest—as much as eight ounces of a four per cent. solution had been used without unpleasant consequences.

The paper will be published later.

PERISCOPE.

IN CHARGE OF WM. E. PARKE, A.M., M. D.

MEDICINE.

Relapses of Typhoid Fever.

Dr. Hugh M. Stewart of Guy's Hospital, London, contributes an article on this subject to the March number of the *Practitioner*, founded in a great part on the clinical histories of fifty cases observed in the hospital. He thinks that so-called relapses are genuine second attacks; that they are due to re-infection (infection in a fresh part of the intestine, always at a lower situation and usually in the large intestine) from the patient's own lesions; that constipation is an important predisposing cause of relapse; that relapses occur at a certain definite period—on the average, after an apyretic interval of a little less than six days for first relapses and a little over thirteen days for second relapses; that relapses are rarely fatal; and that they heightened the patient's immunity from subsequent attacks. While, as has been said, he regards constipation as an important predisposing cause of relapses, he intimates that it ought not on that account be treated, for the reasons that the prognosis in cases of relapse is good, that the recurrence of a relapse probably confers a higher degree of immunity than a single primary attack, and that treatment of constipation may excite a dangerous degree of peristalsis. Intestinal perforation is far less common in a relapse than in an original attack, partly because the infection is less profound, owing to the partial immunity occasioned by the initial attack, and partly because the large intestine, where the lesions of the relapse are prone to be found, is thicker-walled than the small intestine. Relapses run their course more rapidly than original attacks, as regards both lesions and symptoms, and this fact gives rise to the false appearance of all the lesions being of the same duration at the necropsy.—*N. Y. Med. Journal.*

Limitations of the use of Nitroglycerine in Chronic Nephritis.

Dr. D. D. Stewart states that, in his opinion, when it is desired to employ this drug over a considerable period of time for its effects on blood-pressure, the best rule of administration is to so proportion the dose that the intervals are comparatively short—never less than four times daily—and the amount, though sufficient to produce some subjective or objective effect, never more than that just necessary to cause the slightest feeling of fullness in the head or to slightly quicken the pulse. When a rather rapid increase seems necessary to maintain a constant effect, an equally important point is to temporarily discontinue the drug for two or more days, at intervals of two or three weeks. On its resumption a smaller initial dose will be required to produce physiological effects than that last taken.—*Thera. Gazette—Maryland Med. Journal.*

Poisoning by Guaiacol.

The external application of guaiacol for the reduction of febrile conditions has been given a prominent place in recent medical journalism. It is important, therefore, to direct attention to the toxic symptoms in the first fatal case of guaiacol poisoning.

Prof. Oscar Wyss, of Zurich, reports in the *Deutsche Medicinishe Wochenschrift*, of the case of a girl nine years of age, who had been accidently given 5 c. c (75 drops) of guaiacol. In a short time she became unconscious; the conjunctivæ became injected, the corneal reflexes diminished and the pupils no longer reacted to light; there were frequent attempts at vomiting and the saliva flowed from the mouth in large quantities. The pulse became rapid, the sensibility of the skin much diminished. Finally the patient began to vomit; the physician detected the odor of guaiacol. The stomach was washed out, but she did not rally. The cyanosis gradually diminished, and instead of it a deadly pallor was observed; the respiration became frequent. Three and a half hours after the guaiacol had been swallowed the patient had 100 c. c. of brownish-red urine.

The spleen and liver soon enlarged, and the temperature fell to 35.5°C. (96°F.) and small hemorrhages were observed upon the skin of the arms and legs. The urine contained albumen, blood and casts, and Ehrlich's carbolic acid test was positive.

Jaundice soon appeared, the stupor increased and the patient died on the third day.

The autopsy revealed an acute gastritis and enteritis, parenchymatous degeneration of the liver, acute hemorrhagic nephritis, parenchymatous degeneration of the heart muscle, and ecchymoses in the pleura, peritoneum, endocardium and pericardium. The spleen was much enlarged.

Kobert in his text-book on "Intoxicationen" points out that after one gram (15 drops) doses of of guaiacol slight appearances of poisoning may supervene. These are characterized by a burning feeling in the stomach, nausea, etc. In one case in which fifteen grams, (three and two-third drachms) were accidentally taken by a patient in the Dorpat Clinic, the stomach was immediately washed out and the patient was rescued. However, unconsciousness set in, the pupils became contracted, the breathing irregular and the intensely dark appearance of the urine was very noticeable.—*Omaha Clinic.*

Blood-Serum Therapy; Its Evolution and Present Status.

Dr. Carl Gunther (*Deutsch. Med. Wochenschr.*) The author gives a concise review of the blood-serum treatment and the princi-

ples which, at different times, were thought to control its action. The treatment depends upon the idea that the blood-serum of individuals who have artificially been made immune against a certain infectious disease, if introduced into the body of another individual, will develop healing properties or cause immunity from the disease in that person. Gunther describes the different processes by which the cultures can be weakened before being used for injections, and the different hypotheses as regards their action in the body, such as the hypothesis of retention and the theory of phagocytosis. He also mentions the destructive properties which blood-serum itself has on certain bacteria. The serum to be used in treatment can be preserved by the addition of ½ per cent. of carbolic acid. Nothing definite is as yet known about the chemical substances present in the serum.—*American Medico-Surg. Bulletin.*

Severe Hiccough.

Heidenhain (*Berl. klin. Woch.*, June) remarks that this clonic convulsion of the diaphragm may be caused by direct or reflex irritation of the phrenic nerves. Reflex hiccough may be produced by diseases of the peritoneum, stomach, etc. Sometimes it is due to severe cerebral disease. It is observed before death from malignant disease of the intestine. A patient, aged 72, had a severe attack of hiccough five years ago, lasting five days, for which no cause could be found. In the present attack cocaine was given, with the best results, after other remedies had entirely failed. A few days after the attack all the symptoms of intestinal obstruction, including fæcal vomiting, appeared. Abdominal section was performed, and a large mass of growth was found arising from the tail of the pancreas, and surrounding the large intestine. An artificial anus was formed, but the patient soon died. In this case the patient seemed to be in the best of health until he had a slight attack of bronchitis. Five days later the hiccough supervened, and lasted eleven days. Seven days after the cessation of the hiccough intestinal obstruction manifested itself. The author thinks that the hiccough was the precursor of death from intestinal carcinoma. This disease could not, of course, account for the attack five years previously. Attention is drawn to the value of cocaine in this affection.—*British Med. Jour.*

Diagnosis of Appendicitis.

Edebohls (*Amer. Jl. Med. Sc.*) states that as a rule he has found it possible to palpate the vermiform appendix when not diseased, and in chronic inflammation to recognize distinctly the thickened appendix. He thinks that operation should not be undertaken in chronic cases unless the diseased appendix can be felt, nor in acute cases unless either the diseased appendix or the presence of a tumor can be detected. In acute appendicitis it may only be possible to localize precisely the appendix after anæsthesia, but information of much value as a guide to the point of incision may then be obtained. In searching for the appendix, the patient's knees are flexed slightly, and the fingers of the right hand are placed on the abdomen near the umbilicus. The fingers are then drawn from the umbilicus to the anterior superior iliac spine, firm pressure being exerted so that the resistant posterior abdominal wall and the pelvic brim can be perceived distinctly. The appendix is felt as a flattened ribbon-shaped structure when normal, as a more or less rounded and firm organ when thickened by past or present inflammation. The normal appendix exhibits no special sensitiveness, but when inflamed is more or less tender. The origin of the appendix lies generally an inch or half an inch outside the iliac artery, so that the line of the vessel (from the left of the umbilicus to the middle of Poupart's ligament) forms a useful guide to the appendix. Edebohl's observations were nearly all made in women. He found the cæcum empty in nearly every person examined. He has tested his method by observations made during laparotomy, in cases of both normal and inflamed appendix. —*British Med. Journal.*

Hypodermic Injections of Nuclein.

Dr. Victor C. Vaughan, who in common with other investigators has been testing the efficacy of the hypodermic injection of nuclein solutions in pneumonia, tuberculosis, etc., records his results in the *Journal of the American Medical Association*, as follows:

1. The subcutaneous injection of nuclein increases the number of white blood corpuscles.

2. This increase occurs in both healthy and tuberculous persons.

3. With like quantities of nuclein injected, the increase varies with the person. It may be slight, and it may be three-fold.

4. This increase occurs principally in the polynuclear cells.

It is evident as a rule as soon as the third hour after treatment and generally disappears after the forty-eighth hour.

If the nuclein shall prove of any value in the treatment of tuberculosis, it will most probably be due to the fact that they increase the polynuclear white corpuscles.

I have been using nuclein in the treatment of tuberculosis in man since May 1, 1893. At first I employed only yeast nuclein, but now I am using spleen nuclein in some cases. When sufficient evidence has been obtained either to reject or recommend the treatment, the results will be communicated to the profession. I may say, however, that only in initial cases may we expect any benefit, and even in regard to these I must have more abundant material and a longer experience before I can speak with any certainty.

Motion of Human Spermatozoa.

Various authorities state that the spermatozoa may continue to move during twenty-four to eighty four hours after death in the fluids of the seminal tract. Outside the body the movement of spermatozoa has been observed for seventy two hours by Hofmann and Mantegazza for four days at a suitable temperature. Mr. Piersoll now states that at a temperature of 8.5° C. a few of the elements showed movement, after being kept for nine days. These facts show that spermatozoa may long retain their vitality in the female generative tract and must receive in future due consideration in connection with certain medico-legal questions.—*Med. Rec.*

Electricity in Amenorrhœa.

Panecki (*Therap. Monatsh.*,) has found electricity, and particularly the faradic current, the most successful means of dealing with amenorrhœa. It is necessary that the poles should be introduced into the uterus and be allowed to act there. This treatment is well borne, and the current can be increased at each sitting, the number of the latter required averaging from five to thirty, and their duration five to fifteen minutes during successive days. The author's experience includes 18 cases in which the cure of the condition was established a year or more ago, the patients still remaining well. One of these, a married woman aged 31, had never menstruated though she was subject to periodical affections (severe headache, etc.) The treatment on various lines had extended over six years, but with absolutely no success. The author at the expiration of one of these periods commenced the application of the faradic current, and after twenty-eight successive sittings a small flow became apparent. During the following interval six more applications were made, and the patient is now well and relieved of all symptoms.—*British Med. Jour.*

Treatment of Mumps.

Dr. A. Martin (*Sem. Med.*). During a recent epidemic of mumps among soldiers, the author successfully resorted to the following treatment:

From the outset, he instituted buccal antisepsis, which, when rigorously done, according to his observations, diminishes the chances of testicular complication. He therefore had his patients gargle and cleanse the mouth as often as possible with solutions of thymol, carbolic acid, or very hot 4 per cent. boric-acid solution.

Besides, during the first days of the disease he administered antipyrine in daily doses of 2-3 grammes (30 45 grn.). This, he states, more rapidly effects the resolution of the inflammatory process than do sodium salicylate and other remedies; moreover, it acts more promptly on the fever and pain.

In orchitis caused by mumps, pilocarpine subcutaneously in doses of 1 centigramme (1-6 grn.) repeated once daily, is said to have promptly diminished the pain from the first evening on, and to have lowered the temperature, which became normal on the third day. The swelling of the testicle disappeared between the eighth and tenth days. After the acute period of orchitis was passed, the patient was submitted to a tonic treatment (cod-liver oil, nux vomica, cinchona extract, meat-powder, sulphur baths, etc.) for the purpose of preventing testicular atrophy.—*A. M. S. Bull.*

The Influence of Alcohol, Glycerine and Olive Oil on the Action of Disinfectants.

Lenti summarizes in the *British Medical Journal* the results of a series of researches as follows: (1) Alcohol in the absence of water neutralizes all bactericidal power on the part of sublimate or phenol with regard to anthrax spores, and the bactericidal action is not exercised until the dilution of the alcohol with water becomes greater than two per cent. in the case of 1 in 1000 sublimate solution, or than seventy per cent. in the case of carbolic acid. The length of time to which the spores were subjected to the action of the solution was twenty-four hours in the case of sublimate, and forty-eight hours in that phenol. (2) Glycerine has a similar impeding action, interfering with the action even of a 2 in 1000 solution of sublimate, if the proportion of water be less than forty per cent. In the case of phenol it is still more manifest. (3) Phenol and lysol dissolved in olive oil have no disinfectant action when tested as above. (4) In the preparation of a disinfecting fluid one ought, therefore, to avoid the addition either of alcohol, glycerine or fats.

SURGERY.

Trephining for Headache.

At a meeting of the New York County Medical Association held June 18th, Dr. J. Marshal Hawkes presented a patient, a young man, whom he had trephined for persistent localized headache. In Starr's recent work on "Brain Surgery," Dr. Hawkes said it was stated that this operation had been performed but twice for the purpose in question, once in London, and once in New York, by Dr. Robert F. Weir. From early boyhood this patient had suffered intolerably from frontal headache, and though he had consulted a large number of physicians, every remedy that had been tried had utterly failed to give him relief Thinking that the trouble might possibly be due to eye strain, Dr. Hawkes first sent him to Dr. Knapp, but the latter found that there was no difficulty of this kind. On making an examination of the head, the only abnormality that could be detected was a slight indentation of the bone in the right frontal region. As a last resource, Dr. Hawkes determined to trephine at this spot, and on June 30, 1892, a button of bone, about

two-thirds of an inch was removed under strict antiseptic precautions. It was found that in the location named there was a depression of the inner table of the cranial bone, making pressure upon the brain substance, and the button removed was exhibited to the Association. From the time of the operation there had been complete relief from the headache, and as two years had now elapsed, the cure could be pronounced permanent.—*Boston Med. and Surg. Jour.*

Shortening the Round Ligaments.

Kellogg (*Mod. Med.*) has used this operation in over 300 cases in which the uterine appendages had been previously removed. Comparing it with the operation of ventral fixation, he finds its advantages to be as follows:—It supports the organ in a natural way, the traction falling upon the parts accustomed to it and able to bear it, being closely connected with the bony walls of the pelvis, instead of upon the yielding structures at the median line The operation is a safe one; the mortality is nothing. The operation involves no mutilation, no conspicuous cicatrix, no considerable amount of suffering, and has nothing about it of a frightful or repulsive nature. The time required for the operation, when a proper method is employed, is only five to fifteen minutes, according to the skill and experience of the operator, so that the patient is but a short time under the influence of the anæsthetic, involving very little risk of fatal consequences from this cause.

The failures have been less than five per cent. and were not due to any defect in the operation, but to the patient not undergoing the necessary treatment to remove the primary causes of retroversion.

The Bloodless Gradual Dissection Method of Amputation at the Hip Joint.

Dr. W. L. Estes has employed the following method in seven cases, with but one death, and considers it especially adapted to cases which necessitate very short flaps.

The first step in the operation is, by means of an Esmarch bandage, or by elevating the extremity, to force all the blood out, unless the extremity has been so crushed that this is impossible. Secondly, the femoral vessels are tied by double ligatures at Poupart's ligament, and the vessels divided between the ligatures. The rubber band may now be removed. Third, an anterior flap is gradually dissected up from without inward. Great care is taken to secure all known vessels before they are cut, by means of double ligatures or two hemostatic forceps, and all muscular or small branches when cut must immediately be secured. After the capsule is reached anteriorly, the posterior flap is dissected up with the same care as to securing the blood vessels. Finally the capsule is incised and disarticulation is accomplished after the usual methods. The essential feature of the operation is the securing of each vessel before it is cut or immediately after being cut. There is usually no difficulty in securing any vessel except the profunda and internal circumflex arteries. There is no oozing to speak of after this operation, and this feature makes it particularly valuable in very weakened or exhausted cases.

In none of these operations, except the second one and the one before the last, was there more than an ounce of blood lost, and on this account the author calls it the bloodless gradual dissection method.—*N. Y. Polyclinic.*

The Use and Abuse of the Bandage.

T. H. Manley, M. D., in the *Medical Summary:*

As a purely mechanical means of support in infantile or juvenile hernia, a bandage with the aid of a soft muslin pad is of more value as a therapeutic measure of relief and cure, when no complications are present, than any truss that ever was invented or operation devised. In pendulous, flabby abdomens, which permit of a constant strain on the mesenteric ligaments, or those produced by the gravid uterus, kidney or liver, great relief is experienced by the employment of the broad bandage or girth.

The first abuse of the bandage comes through its clumsy, unskilled application, by the inexperienced, hasty or careless. The second, through its too firm adjustment, when the circulation is impeded or as sometimes happens, it is totally strangulated, the tissues beyond becoming asphyxiated, mortified and destroyed. This latter, occurs most commonly, in cases of fracture. As many as five or six such cases have come under my observation in my time, and I have been informed of others, in which the bandage got in its deadly work, though they were frequently entered in the hospital-records as cases of "acute mortification." A fractured limb, which is at all firmly bandaged, should be closely watched, for the first twenty hours; until, in fact, the subsidence of primary inflammation and swelling and the bandage relaxes its grip. It often becomes a matter of great difficulty, to permanently adjust, widely separated fragments, without risking a firm bandage to fix them. These difficulties and dangers could be largely obviated if we would go back to the practice of our fathers; and, carefully adjusting the fracture leave it alone and not permanently "set" it until primary swelling has subsided.—*N. W. Lancet.*

Too Protracted Use of the Bandage.

We daily witness the weakening and atrophic muscular changes which a bandage may produce in that fashionable thoracic girth, commonly known as a "stays" or corset. The maternal binder after parturition, gives great comfort to the bruised, strained, fatigued abdominal muscles, but when too tightly applied or worn too long is

capable of doing mischief. We must then use discrimination, skill and judgment with the roller if we would derive the greatest good from it and avoid the unpleasant consequences to our patients or ourselves, which may attend its injudicious employment.

This is an age when almost nothing takes, if it does not smack of originality. The profession daily hungers and craves for something new; it must have a new coloring or be presented in a new dress, and it is greedily devoured, without our even hesitating for a moment, to determine for ourselves, whether it consists of anything more than a revamped, stale old shell, which may disorder and clog rather than impart vitality or energy.—*N. W. Lancet.*

Treatment of Gonorrhœa.

Dr. Edward Martin, of Philadelphia, after investigating different remedies and methods of treatment of gonorrhœa in a large number of cases, says: Concerning the conclusions which this series of observations seemed to justify, the following is a *resume:*

1. The abortive treatment of gonorrhœa by means of a ten-per-cent solution of nitrate of silver injections applied to the navicular fossa is advisable when the disease is seen in its earliest stage, that is, when inflammatory phenomena are absent, and when the symptoms consist in the slight, whitish discharge and tickling or moderate burning on urination, and when microscopic examination of the discharge shows that it is made up mainly of mucus and epithelium containing little pus. This abortive treatment is successful in an uncertain percentage of cases. When it fails it does not materially complicate the subsequent course of gonorrhœa.

2. When gonorrhœa is first seen in its florid stage, in addition to ordering rest, light diet, regular evacuation of the bowels, free drinking of plain waters, hot baths on retiring, alkaline diuretics, and the treatment appropriate to ardor urinæ and chordee, balsams should be given in full doses, and mild antiseptic irrigations or injections should be practiced at once. The most efficient balsams are sandal-wood and copaiba. These should not be pushed to the point of disordering the stomach.

He uses capsules, each containing:

℞ Balsam copaiba, Oil sandal-wood, āā..... m v.
Oil cinnamon..... mj.

Of these he gives six to twelve per day, administering them one hour after meals.

3. Irrigation of the urethra by means of hot antiseptic lotions gives better results than any other treatment. These should be continued either once or twice a day until gonococci disappear from the discharge or from the clap shreds found in the urine. They should be displaced by astringent injections.

4. When irrigations can not be employed, even during the florid stage, injections are indicated; these should be of bichloride of mercury 1 to 20,000 or nitrate of silver 1 to 10,000. These injections should be gradually strengthened as urethral tolerance is established.

5. Injections of nitrate of silver, 1 to 3,000, or bichloride of mercury, 1 to 1,000, or injection Brow, or any of the formulæ customarily used in practice in the increasing or florid stage of gonorrhœa, distinctly predispose to the development of hyperacute posterior urethritis, epididymitis, and other complications of gonorrhœa, and may aggravate and prolong urethral inflammation. Strong astringent injections employed in the early period of the subsiding stage are equally dangerous.

6. Treatment by internal medication alone is followed by a small percentage of epididymitis and posterior urethritis, but by slow cure. The most efficient treatment consists in the combination of the balsams with local antiseptic washings.—*Therapeutic Gazette.*

Etioloy, Pathology and Treatment of Carbuncle.

Dr. D. W. Graham, of Chicago (*The Journal Am. Med. Ass'n*), in dealing with this important subject, holds that it is in all cases a local disease, and due to micro-organism. The one generally found is the staphylococcus aureus. Sometimes the staphylococcus albus is also found. The coccus may enter through the hair follicles, sweat-glands, sabaceous gland ducts, or abrasions of the skin. The most that a cachectic condition of the body can do by way of etiology is to increase the vulnerability of the tissues. It is also a disease of middle life.

In its anatomy and pathology, it is related to osteo myelitis, parenchymatous abscess furuncle, and acute abscess. The differences in the clinical history and the methods of termination in the diseases of this group are due to the anatomic structure of the region or organ affected. The region frequently affected by carbuncle is the dense, firm, fibrous tissue over the posterior median line of the body. A true typical carbuncle can only happen in such parts of the body as permit of continued surgical tension in the inflamed tissues.

As to the treatment, the writer admits that much good may be done by making an incision into the inflamed part, or by the usual crucial incision. Parker's method of scraping out the inflamed tissue is a good plan. The injection of antiseptics into the swelling cannot be relied upon. The author's plan is to make a crucial incision over the tumour to points just beyond the diseased portion. The integument is raised, and the indurated tissue is then carefully dissected out. The wound is then dressed with some antiseptic. There is very little hemorrhage, and the wound heals rapidly without loss of integument, when the operation is done early.

Excoriations in Children.

In the *Progrès Médical*, No. 16, 1894, the following is also recommended:

Carbolic acid	(grs. xlv)	3.0
Powdered boric acid	(℥iv)	15.0
Powdered alum	(℥iv)	15.0
Precipitated carbonate chalk	(℥ivss)	150 0
Starch	(℥viij)	250.0

—*Pritchard.*

ANATOMY.

Landmarks of the Digestive Tract.

Dr. F. B. Robinson (*Mathews' Medical Quarterly*) says:

1. The sigmoid flexure is a very apt location for disease to arise. In dissecting infant cadavers I find the sigmoid very long and often lying in the right iliac fossa. In one infant, about six months old, I found a volvulus of the enormous sigmoid. The sigmoid and rectum are inseparable. In the sigmoid 60 per cent. of volvulus occur, and men have volvulus four times as often as women. I was unable to produce a permanent volvulus in experimental work on dogs' bowels. When I stitched it the volvulus would unwind and tear out the stitches or lengthen the pedicle. The cause of volvulus is (*a*) fatless, (*b*) elongated mesentery, and (*c*) a history of constipation.

The peculiar disease to which the sigmoid is liable is stricture (malignant or non-malignant). Seventy per cent. of strictures of the large bowel occur in the descending colon; and this would give a large number to the sigmoid, as the sigmoid is some fifteen inches long, and the descending colon proper is only eight inches long. No doubt the frequent stricture of the sigmoid is due to (*a*) the sharp and hard foreign bodies which lie on the sur face of hard fæces, and (*b*) the mechanical d ifficulty of passing through the long, curved gut. A curious feature about man is the sigmoid curve and the rectal ampulla, which must represent some ancient evolutionary stage. A peculiar feature I have long noted in autopsies is that the sigmoid and descending colon are frequently more contracted than the other portions of the large bowel.

2. The splenic flexure of the colon is peculiar from being the most fixed and most acute flexure of the digestive tract. It is held firmly in position by the costo-colic ligament. The sharpness of the bend in the colon at the spleen offers considerable mechanical difficulties to the passage of hard fæces, and this accounts both for malignant and non-malignant strictures at this point.

Rough hard fæces wound the mucous membrane and allow infection to travel through the gut-wall into the peritoneum, and this wound being kept constantly irritated results in inflammation or malignant growths. The inflammatory products organize into connective tissue, ending in contraction or stricture. Tumors and strictures are difficult to diagnose in the splenic flexure, as they are very high under the ribs, and in laparotomy for intestinal obstruction are often overlooked.

3. The hepatic flexure does not give rise to much intestinal disease. It is not an acute flexure, but possesses a very large angle. Its main difficulty is that it is near the gall bladder, which frequently gives rise to inflammation, and it spreads to the hepatic flexure. It is held to the liver by the hepato-colic ligament. Besides being an obtuse flexure, the fæces are not so solid as they are in the splenic and sigmoid flexures.—*American Lancet.*

BACTERIOLOGY.

Microbicide Properties of Mucus.

The presence of vast numbers of microbes in those cavities of the body which are in communication with the air would doubtless be the occasion for frequent and fatal attacks of illness were it not for the fact that the mucus which covers these exposed surfaces is possessed of distinct bactericide properties. Even germs as virulent and tenacious of life as are the spores of the anthrax, have been found to be killed after a few hours of exposure to nasal mucus. This product of gland-action is found to be capable of destroying all kinds of microbes. It is this protective action of mucus which prevents an enormous development of bacteria in the nose and other cavities of the body which are exposed to the air. This fact emphasizes the importance of preserving intact the much-neglected nasal mucous membrane, since it is evident that a state of disease capable of destroying the mucous glands, and hence vitiating the mucous secretion or causing its entire loss, must expose the body to attacks of disease from which it might otherwise escape.—*Modern Medicine.*

PHYSIOLOGY.

The Effects of Smoking Upon Muscular Work.

Prof. Vaughn Harley, M. D., M. C. P. and Grover Research Scholar, publishes in a recent number of the *Journal of Physiology*, the results of an extended series of experiments in relation to causes which influence muscular work. Among the various experiments undertaken by Prof. Harley, some of the most interesting relate to the influence of tobacco-smoking upon muscular work. The idea is generally prevalent among smokers that a larger amount of work can be accomplished under the influence of tobacco than without it,—at any rate, that smoking, even if it does not increase muscular power, lessens the sense of fatigue, and thus enables the individual to continue working longer than he otherwise could do. Prof. Harley's experiments had relation to two points:

1. The amount of work which could be accomplished; and—

2. The length of time during which work could be performed before the point of abso-

lute fatigue, with inability to continue work, was reached.

He found, as the result of his experiments, that even moderate smoking in a person accustomed to smoking so that the primary toxic effects of the nicotine were eliminated, the amount of work which could be accomplished was not increased, and that the approach of fatigue was not retarded. Tobacco-smoking, on the contrary, to use the words of Prof. Harley, "slightly diminishes muscular power and hastens the onset of fatigue."

GYNECOLOGY.

Intra-Uterine Electro-Therapeutics.

Intra-uterine electro-therapeutics (galvanism, faradism, or the sinusoidal current) skillfully, and patiently applied, deserves to remain at the head of gynecological conservative therapeutics.

1. Because it produces as a rule a symptomatic improvement which is oftentimes nearly equal to a cure. This is seen in its action on endometritis and the principal functional troubles. It is wonderfully efficacious in non-cystic tumors. It is often though not always useful in non suppurative peri uterine inflammation. It is useless in cystic collections of any kind whatever and in suppurative pelvic lesions.

2. In cases where it is of no value as a curative agent it may be of the greatest help in clearing up a doubtful diagnosis and settling the question as to whether or not an operation is desirable.

3 If its action is favorable, it frequently gives to sterile women the ability to conceive and bear children. In this connection electro-therapeutics is not hostile to surgery but on the contrary is a most important adjuvant to it, by pointing out clearly the indications for operation and also by completing what the latter has begun, but is not always able to finish—the entire restoration of the patient to health.—Dr. Apostoli in *Trans.-Journal of Electro-Therapeutics.*

CLIMATOLOGY.

The Physiological Effects of Mountain Climates.

Dr. C. T. Williams (London *Lancet*) says: The physiological effects of mountain climates, as shown on healthy or sick persons ascending from the lowlands, are briefly the following: The skin is tanned by the solar rays, and especially by the ultra-violet rays (Bowles); the circulation is at first quickened and the heart's impulse increased in power, but at the end of six or eight weeks the pulse rate becomes less rapid, and it eventually is slower than normal. Respiration is at first quickened, but coinciding with the pulse-rate becomes slower and also falls below the normal, the inspirations being deeper and the expirations (Ruedi) more complete. The quickening of the circulation and respiration is accompanied by thirst, by a reduction in the urea excreted by the kidneys but more carbonic acid (Marcet) and water are eliminated from the lungs, as might be expected from more oxygen being inhaled. Later, when acclimatization is complete, the normal amount of urea is again excreted, and the blood pressure increases. Coincidently with the slowing of the respiration, there is an extension of the thorax in several directions, causing an increase of the circumference measurements of from one to three inches, with increased mobility of the chest walls. All this points to greater physiological activity of the pulmonary organs, from the necessities of a rarefied atmosphere leading to greater development, and it must be noted that all mountain races have large and deep chests and are able to march great distances and to climb mountains with comparative ease. The effect of high altitude climates on healthy persons is excellent, and on most forms of phthisis it has been shown by my statistics to far surpass in results any other set of climatic agents. At the same time this is a two-edged weapon, and in many cases of disease, such as those of the heart, liver, and brain, and in emphysema and bronchitis, as well as in the case of the aged and of those with weakly constitutions, it must be avoided as most harmful. Finally, mountains are highly to be recommended as play-grounds for the mentally tired workers and for the young, who can rest their brains and work their muscles, and by inhaling pure, aseptic air may renew health and vigor and return to their duties refreshed as well as recreated.—*American Lancet.*

ARMY AND NAVY.

CHANGES IN THE U. S. ARMY FROM JULY 15, 1894, to JULY 28, 1894.

Leave of absence for two months is granted Captain Richard W. Johnson, Assistant Surgeon U. S. Army.

The leave of absence on surgeon's certificate of disability, granted First Lieutenant Frank T. Meriwether, Assistant Surgeon, is extended two months on surgeon's certificate of disability.

By direction of the Secretary of War, the order assigning Captain George McCreery, Assistant Surgeon, to duty at Fort Washakie, Wyoming, is revoked.

By direction of the Secretary of War, the order assigning Major Curtis E Price, Surgeon, to duty at Fort Custer, Montana, is revoked, and he is granted leave of absence for one month to take effect, upon being relieved from duty at Fort Porter, New York.

CHANGES IN THE U. S. MARINE HOSPITAL SERVICE, FOR THE FOUR WEEKS ENDING JULY 21st, 1894.

Carmichael, D. A., Passed Assistant Surgeon; Granted leave of absence for thirty days, July 20, 1894.

Glennan, A. H., Passed Assistant Surgeon; to inspect unserviceable property, at Delaware Breakwater Quarantine, July 6, 1894

Bratton, W. D., Passed Assistant Surgeon; to report at Bureau for temporary duty, June 27, 1894.

Kinyoun, J. J., Passed Assistant Surgeon; to proceed to Cape Charles Quarantine, for special temporary duty, June 30, 1894; designated to represent Department at International Congress of Hygiene and Demography, July 9, 1894; to inspect unserviceable property at Boston, Mass., July 17, 1894.

Geddings, H. D., Passed Assistant Surgeon; to report at Bureau for temporary duty July 20, 1894.

Wertenbaker, C. P., Passed Assistant Surgeon; to proceed to Delaware Breakwater Quarantine for special temporary duty, June 30, 1894.

Young, G. B., Passed Assistant Surgeon; to inspect Quarantine Stations, July 20, 1894.

PROMOTION.

B. W. Brown, Assistant Surgeon, commissioned as Passed Assistant Surgeon, July 19, 1894.

NEWS AND MISCELLANY.

State Board of Medical Examiners of New Jersey.

A. K. Baldwin, M. D., president; Wm. Perry Watson, M D., Secretary; A. H. Worthington, M. D., treasurer.

Wm. L Newell, M. D., Millville, examiner in Materia Medica and Therapeutics.

F. B. Lane, M. D., East Orange, examiner in Chemistry, and in Eclectic Materia Medica and Therapeutics.

Wm Perry Watson, M. D., Jersey City, examiner in Practice of Medicine, including diseases of the skin, nose and throat.

A. K. Baldwin, M. D., Newark, examiner in surgery, including surgical anatomy and diseases of the eye, ear and genito-urinary organs

A. Uebelacker, M. D., Morristown, examiner in anatomy.

E. L. B. Godfrey, M. D., Camden, examiner in Obstetrics and Gynecology.

Edwin DeBaun, M. D., Passaic, examiner in Physiology.

G. F. Wilbur, M. D., Asbury Park, examiner in Histology, Pathology and Bacteriology.

A. H. Worthington, M. D., Trenton, examiner in Hygiene and Medical Jurisprudence, and in Homœpathic Matera Medica and Therapeutics.

REQUIREMENTS FOR LICENSE TO PRACTICE MEDICINE AND SURGERY IN THE STATE OF NEW JERSEY. 1894-95.

All requirements for admission should be completed at least two weeks before examination.

They are as follows:

1. Evidence that applicant is more than 21 years of age.

2. Certificates of moral character from not less than two physicians in good standing, one of whom must be a resident of this State.

3. Candidates must be graduates from an accredited literary or scientific college, or have completed satisfactorily not less than a three years course in an a accredited high school or academy, or have received a preparatory education covering the following branches, viz: Orthography, arithmetic, English grammar and composition, geography, history of the United States, algebra and physics, as certified by the State Superintendent of Public Instruction of New Jersey.

4. Candidates must have "received a diploma conferring the degree of doctor of medicine from some legally-incorporated medical college (which in the opinion of said board was in good standing at time of issuing said diploma) in the United States, or a diploma or license conferring the full right to practice all the branches of medicine and surgery in some foreign country, and has also studied medicine four years, including three courses of lectures in different years in some legally incorporated American or foreign medical college or colleges prior to the granting of said diploma or foreign license; provided, however, that two courses of medial lectures, both of which shall be either begun or completed within the same calender year, shall not be considered to satisfy the above requirements."

First Exemption: Evidence of one year's service "as a member of the resident medical staff of any legally-incorporated charitable or municipal hospital or asylum" or of five or more years reputable practice of medicine and surgery may be accepted as equivalent to one year's study of medicine and surgery.

5. "All examinations shall be written in the English language, and the questions and answers shall be, except in materia medica and therapeutics, such as can be answered in common by all schools of practice; if the applicant intends to practice homeœpathy or electicism, the members of said board of those schools respectfully shall examine said applicant in the materia medica and therapeutics of the school in which such applicant intends to practice; the examinations shall be in the following subjects, namely, (Sec. 1.) materia medica and therapeutics; (Sec. 2.) obstetrics and gynecology; (Sec. 3.) practice of medicine, including diseases of the skin, nose and throat; (Sec. 4.) surgery, including surgical anatomy and diseases of the eye, ear and genito-urinary organs; (Sec. 5.) anatomy; (Sec. 6.) physiology; (Sec. 7.) chemistry; (Sec. 8.) histology; pathology; bacteriology; (Sec. 9.) hygiene; medical jurisprudence."

Second Exemption: "Applicants examined and licensed by or who are or have been members of state examining and licensing boards of other states, upon the payment of fifty dollars to the treasurer of said board and on filing with the secretary of said board a copy of his or her license or certificate, certified by the affidavit of the president and sceretary of such board, showing also that the standard of requirements of said board at the time of said license or certificate was issued was substantly the same as that required by said board, and of his or her affidavit as to the personality thereof, may be granted a license by said board without further examination thereby."

COMBINED MOTOR AND PSYCHICAL EPILEPSY; REPORT OF A CASE.

WILLIAM PHILIP SPRATLING, M. D.,* New York.

Our constantly increasing knowledge of epilepsy is causing us to construct a more elaborate classification of the forms of this disease. Up to within a comparatively recent period we were satisfied with the simple division of epilepsy into *Grand Mal* and *Petit Mal;* a designation at once simple and classical.

In 1877, Weisse recognized and described a condition that he termed psychic epilepsy. His description of the new type was based on the observation of four cases.

In psychic epilepsy we recognized a special form of the disease, running a typical course, and in which the convulsive attacks were replaced by peculiar psychoses which bore no relation to convulsions of the ordinary kind. In psychical epilepsy or the psychical epileptic equivalent, as it is frequently termed, there is a peculiar condition of transferred or perverted consciousness, if I may so characterize it. The unconsciousness that usually follows attacks of *Grand Mal* or *Petit Mal*, is not present, yet normal consciousness is seriously interfered with. Those who regard the loss of consciousness as the essential feature of epilepsy will experience great difficulty in properly classifying the psychical form of that disease. More than that they would hesitate to even accept it as a distinct type of epilepsy.

The chief distinction, however, (accepting the involuntary nervous discharge from the cortex as the cause of epileptic phenomena) lies in the fact that in psychical epilepsy those areas which preside over the higher conscious actions of the mind are chiefly involved; while in ordinary epilepsy those areas that preside over motor functions suffer most.

In the first instance, the areas that preside over the higher conscious actions of the mind suffer in varying degrees. The shock that disturbs them may be so slight as to cause only momentary unconsciousness without convulsive symptoms of any kind whatever; or, the shock may be so severe as to be felt by adjacent areas and so give rise to much more marked symptoms. Acute maniacal manifestations even may mark the psychial explosion.

Psychial epilepsy is similar in some respects to *Petit Mal;* the chief points of similarity being the brief duration of the two diseases, and the momentary unconsciousness that is common to them both.

A notable difference between them lies in the fact that *Petit Mal* is frequently preceded by an aura of some kind, while psychical epilepsy is not preceded by permonitory symptoms of any kind whatever. Moreover, *Petit Mal* is a common disorder, while psychial epilepsy is rare.

Dr. M. Allen Starr relates the case of a man who suffered first from attacks of *Grand Mal*, and then from psychial epilepsy. Attacks of the following kind occurred almost daily. "While the patient is walking, reading, talking, or at his

*Formerly First Assistant Physician, N. J. State Hospital at Morris Plains; Member New York County Medical Society; Member Harlem Medical Association of the City of New York.

professional work, he will suddenly cease what he is about, and his face will assume a broad grin for about ten seconds, then he looks about in an absent-minded way, and immediately resumes his occupation. At these times there is no apparent loss of consciousness; he never staggers if standing, nor lets anything drop which he is holding; but when questioned as to what has amused him, he has no recollection of being amused, or any notion that anything unusual has occurred."

"These attacks," Dr. Starr adds, "are undoubtedly of the nature of *Petit Mal*, but the fact of the change of mental expression seems to indicate that when they occur, there is present a second state of consciousness in which the patient perceives something funny; just as in the maniacal conditions there is a second state of consciousness in which the mind is excited by frightful perceptions and notions."

The case which I have to report is that of W. H., a sailor, fifty years of age, who came under my observation in February last. He has had epileptic attacks since he was twenty-five years old. He is well-built, vigorous and active, and manifests no evidence of mental deterioration as the result of having suffered from epilepsy for twenty-five years. The patient cannot recall that any of his immediate ancestors suffered as he does, or that any of them were ever insane.

He has never received an injury of any consequence, on the head. His skull is entirely free from indentations, and the scalp shows no scars. About the time of the first attack he indulged moderately in alcoholic drinks. He admits specific infection, which occurred prior to the first convulsion; though all evidences of syphilis are lacking at this time.

The first attack came on twenty-five years ago, and was very severe. It came on during the night. Twenty-four hours after the first attack he had another more severe than the first. This was followed by post-epileptic mania that lasted some hours. A period of several months passed after this in which he had no attack. Then a mild one occurred during the night.

During the following twenty years he continued to suffer at long intervals; many months often intervening between the attacks. He noticed during this time that the attacks were far less frequent while he was at sea, than when he was on shore. He mentions especially one cruise that lasted a year, during which time he did not have a convulsion. In less than twelve hours after going on shore he had a violent seizure. The radical change in his manner of living, change of diet, and indulgence in certain excesses, undoubtedly caused a recurrence of the trouble.

Up to five years ago, he had attacks of *Grand Mal* only; and they were always nocturnal. At that time he began to experience seizures of entirely a new kind. These always came on during the day, and partook of a psychical nature from the first. During the past five years he has had almost daily an attack similar to the following. When reading, writing, walking, or engaged in any form of light employment he will suddenly stop what he is doing, and if walking will turn half around; appear dazed and confused; partly extend his hands like a person groping in the dark, his face wearing all the while a completely changed expression. He does not fall or even stagger; makes no noise or outcry of any kind; there is no change in the color of his face, and no change in the condition of the pupils. This condition lasts from five to seven seconds, and passes away as quickly and as suddenly as it came. He knows nothing of it afterwards, and denies that he has acted strangely.

His expression often assumes a frightened and apprehensive look during the brief seizures. If the attack comes on while he is at the table eating, he suddenly stops using his knife and fork, stops masticating his food, his face takes on a changed expression, and then he suddenly begins eating as before, totally unconscious of what has occurred. He has never had an aura of any kind, and it is a singular fact that the epileptic who suffers from the psychical type of that disease enjoys immunity in that respect.

This patient often experiences as many as three seizures in twenty-four hours. In addition to the psychial attacks, which are always diurnal, he continues to suffer from violent attacks of *Grand Mal*, which are always nocturnal.

Recently he has manifested very positive symptoms of post-epileptic mania. This condition comes after each seizure, and usually lasts from three to four hours.

As to treatment there is but little to be said. The medical treatment of his case was as unsatisfactory as it is in the vast majority of epileptics. Liberal doses of bromide of potassium, in combination with choloral hydrate, given at nine o'clock in the evening, lessened the force and violence of the night explosions more than any other remedy.

The most important part of the treatment in his case, however, consists in the most rigid and careful supervision of his diet. Indulgence in indigestible foods and alcholic drinks, always increased the frequency and violence of his convulsions.

COMMUNICATIONS.

OVARIAN SARCOMA; DISPLACED KIDNEY; ECTOPIC GESTATION*

E. E. MONTGOMERY, M. D.†

GENTLEMEN: The patient I bring before you to-day is 23 years of age; puberty occurred at 14; menstruation was regular though attended with pain, particularly during the last twelve months. She is married and has no children. For the last year she has been complaining of severe pain in the right iliac region during menstruation, but was not aware of any enlargement of the abdomen until her attention was called to it by her mother and a physician, who told her she had a tumor. Her general condition was good until two months since. She has been suffering from constant pain, unable to sleep without anodynes, for the last month slept sitting up in bed, which increased the tension of the abdominal wall, but decreased the pain. She has been in the ward a few days. The abdomen, as you see, is considerably enlarged. Palpation, even when carefully practiced, is attended with a great deal of pain and discomfort. There is a mass situated in the lower part of the abdomen, which is movable, dense and hard. When we come to consider a growth of this kind, we naturally inquire as to the possible organs from which it may have arisen. We recognize that a growth situated in the lower part of the abdomen probably arises from the pelvic organs. The ones which are most likely to produce such growths are the uterus and ovaries. Solid growths in this region generally arise from the uterus, so when we find a mass which is firm and resisting, we at once form the conclusion that it is a growth from that organ. Examining by the vagina, we find the uterus turned backward, quite movable, not apparently connected with the growth. In additon to that, we find the mass, being movable, is associated with a certain amount of ascites. The growth has attained to a considerable size. The fact that the uterus is not associated with it leads us, of course, to realize that we have not a fibroid tumor of that organ. We come then to consider the character of growths which are likely to develop in the ovary. The great majority of tumors of the ovary are either glandular proliferating or papillary proliferating tumors, either of which may attain to considerable size. These tumors, however, have more or less sensation of fluctuation; rarely, unless the cysts are small, are we led to believe the growth is a solid one. Solid tumors of the ovaries are fibromata and sarcomata. Fibroid tumors of the ovary, however, rarely attain to large size. Large solid tumors of this organ are usually sarcomata. These are also associated where they have attained a considerable size, with more or less irritation of the peritoneum, which results in the presence of ascites, so that we have here in this patient a tumor which has attained a considerable size, which from its sensation is evidently a solid growth, one which is not sufficiently connected with uterus to indicate that it has arisen from it and is consequently, quite probably, an ovarian growth. The association, then, of these circumstances, its solidity, its size, and the presence of

*Clinical lecture delivered at the Jefferson Hospital, April 3, 1894.

†Professor of Clinical Gynecology, Jefferson Medical College; Gynecologist to Jefferson and St. Joseph's Hospitals; Obstetrician to Philadelphia Hospital; President of Alumni Association, Jefferson Medical College.

ascites, leads us to believe that we have in this patient a sarcoma of the ovary. The result of operation on ovarian sarcoma is not so favorable as with a tumor of a more benign character, yet where a tumor of the ovary is present and there is no indication of the extension of the disease through the pedicle to the deeper structures, we may hope for a successful removal. As I place my hand over the abdomen I find this mass is quite large, extends above the umbilicus and is so large that it rests upon the pelvis, that it is hard and resisting, indicating its character to be either a fibroid or sarcoma. The reasons for this latter conviction I have already given. We carefully cleanse the abdominal wall with alcohol, although it has been shaven and the parts thoroughly washed with soap prior to the administration of the anæsthetic. We will have to make an extended incision here, as this is quite a large mass to bring through. As we open the peritoneum, we see at once an escape of the ascitic fluid. In all operations it is important to watch carefully as we proceed, not to injure the bladder, as it is sometimes situated higher than normal. I was so unfortunate some years ago in an operation upon a case, to open the bladder, but immediately closed it with sutures and the patient experienced no inconvenience. As we look at the mass, we find the upper part of it is quite friable, easily broken down, so it is necessary to make our incision rather longer in order to readily bring it out. As it is somewhat friable, after having brought it out we grasp the pedicle with a pair of forceps, and cut away the tumor, leaving the ligation to follow. I ligate this pedicle with silk, using just as thin silk as will bear the necessary traction upon it, so we will leave no more foreign body in the abdominal cavity than is absolutely necessary. Having removed the one ovary, we examine carefully the condition of the other, and as I do so I also look to see the condition in the appendix vermiformis. As there is no sign of disease in either, we will proceed to close the wound. The right ovary in this case is completely atrophied, being not more than one-third its normal size. As there are but few adhesions and the cavity is perfectly clean, we will close the wound without drainage. In closing the abdominal walls we are particularly careful to introduce our sutures in such a way as to bring in apposition the different layers of tissue, aponeurosis in contact with aponeurosis, muscle with muscle. Before closing, as the muscle is a little ragged, the edges are trimmed off. Before the sutures are tied we ascertain whether we have removed all our sponges. It is very important to make sure of this, as it is a very unpleasant accident to have them remain. I am in the habit of using a gauze sponge as you see. Recently a very unfortunate experience occurred. I had directed that twelve gauze sponges should be placed in the basin for the operation. After the operation was completed, the sponges were counted and we found thirteen. Naturally, we were then uncertain as to whether we had all the sponges or not. Careful examination revealed no more in the abdomen. The patient did well until the end of ten days, when an elevation of temperature occurred, and an abscess formed in the line of the wound. At the end of some three weeks, in looking into the sinus, I saw something that had a suspicious look, and with a pair of forceps raised up a piece of one of our gauze sponges. This was removed and the patient recovered, but it has taught me a lesson not to depend upon others, but to see the sponges counted, both before and after the operation. In tying the sutures, do not tie them too tightly. Where they are drawn very tight they produce sloughing of the enclosed tissues, and if there is any possibility of infection, suppuration will necessarily result. I have seen gentlemen in closing the abdomen, make as much traction upon the sutures as if tying an artery. You want to tie them in such a way as to hold the surfaces firmly in apposition but not make undue pressure. Superficial sutures will be introduced where necessary, to hold the skin in apposition. The wound is carefully cleansed, dried, a layer of gauze placed over it, which is sealed down with collodion, and its surface dusted with a mixture of iodoform and boracic acid. Over this sublimate gauze is placed and a thick layer of sterilized cotton, which is held in place by strips of plaster and tapes, and finally a bandage. The patient will not be given anything by the mouth for twenty-four hours. Rectal enemata of

half a pint of salt solution with thirty drops nux vomica, will be given every three or four hours. These enemata have an influence similar to transfusion and allay the intense thirst from which these patients suffer. With the action of the nux vomica we increase the peristaltic movement of the intestines and favor the more rapid evacuation of gas.

DISPLACED KIDNEY.—The next patient is a woman 38 years old. She had an abdominal section done two years ago in an institution in this city, for what purpose I am not aware. You see the cicatrice of the incision, which presents a slight hernia. The patient complains of a lump in the left side. This is situated a little below the line of the umbilicus, and we will make a careful examination of it. I recognize it from its shape and outline to be the kidney. It is evidently a displacement of the left kidney. Not unfrequently we find patients who have had large abdominal growths removed, or where a woman has been very fleshy and subsequently become very thin, the kidney becomes displaced. This sometimes gives rise to very marked nervous phenomena, palpitation of the heart, disagreeable sensation in the abdomen, sinking and rapid pulse. These peculiar symptoms have been attributed to the traction of the displaced organ upon the brain of the abdomen, the solar plexus. From the appearance and outline of this mass, the peculiar sensations to which this patient has been subjected, I have no doubt that this is a displaced kidney.

ECTOPIC GESTATION.—You remember one week ago I brought a patient before you and made a diagnosis from the general appearance of the mass and history of the patient, that we had an extra uterine pregnancy. You will remember there were some difficulties in diagnosis due to the fact that while the tumor was quite large, no solid material could be discovered; that it gave a sensation of fluctuation and yet there was distinct resonance over its entire surface. This resonance was lower in tone than over the intestine, indicating that it filled a large cavity. You will remember that it was a question if we had an ectopic gestation, why should we have resonance; and the reply I gave was that as the fetus had been dead for some length of time, decomposition had occurred in the sac and the presence of gas thus formed produced this resonance. The tumor was situated behind the uterus and extended above it, pushing the uterus up over the symphysis, and the tension was so great on the sac that it was extremely difficult to say that we had not to deal with part of the uterus. The mass might be a retroflexed, impacted, pregnant uterus, the fetus still within its cavity; but the entire history led us to believe we had to deal with an ectopic gestation. The patient was operated upon the following Friday and on opening the abdomen we saw a large fleshy mass, which closely involved the intestines and was situated posterior to the uterus. This mass was opened into and at once there was a discharge of foul liquid and the parts of the fetus were recognized, seized and withdrawn. The placenta was attached to the anterior part of the sac so it could be entirely removed. The sac itself, involving, as it did, the intestines and the uterus, was impossible of removal, so that the parietal peritoneum was stitched to its surface and the sac cavity packed with iodoform gauze. Although this patient had a temperature prior to the operation of 104 degrees, at no time subsequently has it exceeded 100 degrees. Her convalescence is as rapid as could possibly be expected.

OVARIAN CYST; OVARIOTOMY.

I bring before you a young woman 19 years of age, who was in fairly good health until about three or four months since, when she began to experience distress and pain in one side, and as I expose the abdomen you notice there is considerable enlargement. I had the patient before you a week ago to-day and made a diagnosis of ovarian cyst for the following reasons: The protrusion is more marked particulary at the lower part of the abdomen. If we had ascites or fluid free in the abdominal cavity we would find it would be larger from side to side, and there would not be so marked prominence at the lower portion. We would also find in percussing over such an abdomen that there was resonance at the summit of the swelling, while in this it is dull over the entire swelling and resonant in the flank above, indicating that the fluid is confined within the sac. It is true we might have such an enlargement arising from a fibroid tumor, but in that

case we would not have fluctuation. You will ask may we not have absence of resonance in ascites. Yes, in those cases in which the distension is so great that the mesentery is too short to permit the intestines to float to the surface, or where due to some inflammatory condition the mesentery is shortened and the intestine bound down; but even in such cases we may be able to depress the abdominal wall, displacing the intervening layer of fluid and secure resonance by deep percussion, we are superficially afforded dulness. Having determined the fact that we have an ovarian cyst, we have assured this patient the only means for her relief and radical cure is by its removal. We have prepared this patient in the ordinary method for the operation by clearing out the alimentary canal, giving her liquid diet for the last twenty-hours, had the abdomen shaven, carefully cleaned, and a bichloride pad applied over it. As a final preparation, before making the incision we will scrub the abdomen with alcohol. An incision is made through the skin and superficial fascia down to the aponeurosis and the muscle. We endeavor as nearly as possible to strike the linea alba. This may be accomplished by making a slightly oblique incision through the aponeurosis, which will demonstrate the position of the muscular septum, when the incision may be completed through it the length of the external portion. The peritoneum is opened carefully, in order not to injure the cyst, and it should be remembered that it is possible a loop of intestine may be fixed between the parietal peritoneum and the cyst surface. Having opened the peritoneum we see the smooth, pearly, glistening surface of the cyst. If this were a uterine tumor we would find it presenting a red, flesh-like appearance, instead of this pearly, glistening surface. The trocar is driven through the sac wall, its contents emptied, the sac grasped with cyst forceps and drawn out as it empties. As there are no adhesions, the cyst is readily withdrawn. A couple pair of pedicle forceps are applied to its neck and the cyst cut away. The intestines are covered and held back by gauze pads. We now proceed to secure the pedicle. This we do by transfixing it with a piece of silk, using for this purpose as fine a ligature as will serve the purpose to firmly secure it. It is unnecessary to use heavy cable silk for this purpose. The firmer the silk ligature, the earlier will it disintegrate, and the less likely is it to give rise to trouble. Having removed the one ovary we now ascertain the condition of the other. This should always be done for the reason that we may have a large cyst in one ovary and the other one destroyed by cysts as well, and if the abdomen were closed without its examination or removal, the patient might have to undergo a second operation within a short time. As I raise the other ovary up, we find it also contains a cyst. This does not, however, involve the entire tissue of the ovary, and as this woman is but 19 years of age, it does not seem desirable to sacrifice both ovaries if it is possible to save one, so I propose to split this ovary, dissect out the cysts and then close it with sutures, in this way giving the patient one ovary that will be of service. A few years ago, in operating upon this case, I would have taken out this ovary on account of the cysts it contains, but I have several times of late done the operation I now do, that is, resect the diseased portion of the ovary and leave the healthy portion remaining. In one case the patient subsequently became pregnant and it has been a great source of comfort to me to know that I have resorted to this operation and have not rendered the patient completely sterile. The wound is closed by a single row of silkwormgut sutures so applied as to accurately appose the wound service. As no drainage has been used we will apply a piece of gauze, seal down its edges with collodion, and dust the surface with iodoform and boracic acid, over this apply additional gauze and cotton, which is held in place by pieces of plaster with tapes attached; over all, a bandage. This patient will not be given anything by the mouth for the next twenty-four hours, but she will have administered, every three or four hours, half a pint of warm water in which half a drachm of chloride of sodium is disolved and thirty drops tincture nux vomica added, per rectum. Salt solution acts somewhat as a transfusion and as it is absorbed, it decreases the amount of thirst the patient experiences, and in those cases in which there has been a severe loss of blood, diminishes shock. Nux vomica stimulates the contraction of the bowel, increases the probability of early discharge

of gas, and consequently decreases the tendency to tympanites. If there is any elevation of temperature, the patient will be given salines with a view of early evacuation of the bowels. If the stomach should be irritable, a combination of saline and calomel should be given, as the latter she cannot readily vomit. In this way we make the intestines drain the peritoneum. Ordinarily the patient undergoing such an operation does not experience any special inconvenience, and no purgative will be given unless about the second or third day, when preferably an enema consisting of an ounce each of magnesia, glycerine and hot water will be given.

At the close of the clinical work of the session, I take pleasure in congratulating you upon the amount of work you have been able to see. In the general and special clinics, some three ovariotomies have been done, a number of operations for removal of appendages, operations for laceration of the perineum, for vesico-vaginal fistulæ, recto-vaginal fistulæ, removal of the uterus through the vagina, and a sacral resection, in which the rectum, uterus, ovaries, tubes, posterior wall of the vagina, and perineum were removed. You will appreciate your advantages when I tell you my term of two years as a student in this institution, I saw but one ovariotomy and that patient promptly died from peritonitis. I saw one operation for laceration of the perineum, which consisted of denuding the outside of the vulvar orifice and closing it with a quilled suture. The gynecology we then saw consisted principally in the introduction of the speculum, exposing the cervix, passing a sound and then introducing a piece of nitrate of silver, which was permitted to remain in the canal.

THE TREATMENT OF DIABETES MELLITUS.*

DR. H. BARTH, PARIS, FRANCE.

At the out-patient department this mornimg you saw a patient with diabetes mellitus who will serve as the text of an attempt to trace the outlines of the treatment of diabetes mellitus as have been drawn from clinical experience rather than from the uncertain experiments of physiology.

Our patient is a man of seventy-one years, a tailor by occupation; he leads a sedentery life but is sober, and presents no antecedents worthy of note. For the last two or three years he has noticed a decrease in strength which he attributed to his age. Soon this was followed by neuralgic pains, at first limited to the head and face, then extending to the precordial region and, finally, to the abdomen and the kidneys. It is especially of this lumbo-abdominal neuralgia that he complains. It is bilateral and occupies symmetric points in both sides. Besides this he complains of cramps in the calves of his legs; during the past six months his waist has increased greatly in circumference; he easily becomes fatigued and out of breath at the least effort; finally, his virile powers, which had remained intact till then, have nearly entirely disappeared, a feature which he especially dwells upon.

This man has not the air nor appearance of an old man, for he is remarkably well preserved for his age. His face is ruddy, his form well rounded and his hair is scarcely turning gray. Examination of the internal organs revealed nothing abnormal, and the diagnosis would have remained *in suspenso* had we not, as is our usual habit, analyzed his urine. Here we discovered a very pronounced glycosuria, he excreting about eighteen grams of sugar per litre. Yet the patient is not troubled with great thirst, his appetite seems moderate; he only urinates three times during the night, and the quantity of urine is but little increased. In short, the disease in question is one of the latent form, a functional disturbance, whose cause must be discovered and righted before nutrition has suffered severely. What therapeutic measures have we employed in this case?

Before detailing them let me recall to you in a few words what we know of the pathological physiology of diabetes melli-

*A clinical lecture delivered at the Hospital Broussais, Paris.—Translated for THE MEDICAL AND SURGICAL REPORTER by F. H. Pritchard, M. D.

tus; these short outlines will permit us to point out the principal indications and to pass in review the corresponding therapeutic measures.

Without attempting to discuss the theories advanced which still rest upon uncertain arbitrary bases, it it safe to consider diabetes mellitus as due to a disturbance of nutrition dependent upon an exaggerated activity of the glycogenic function of the liver, while, at the same time, there is a absence of the moderating influence of the pancreas through its secretions. This double disturbance may be the result of a primary lesion of the nervous system. It appears most easily, or its effects are more manifest, in those subjects in whom interstitial combustion is defective, and whose organisms are incapable of using up the sugar formed, in excess. Therefore gouty and arthritic patients, as we know, are particularly liable to diabetes.

The accumulation of unused or unburned sugar produces an excess of this substance in the blood which, in turn, stimulates the secretion of urine, and the excess of sugar passes out from the body through the kidneys as soon as it is formed. In the benign forms this elimination suffices to prevent any grave functional disorder and the organism is enabled to repair its losses by abundant alimentation. But, in the grave cases, the equilibrium is kept up with difficulty, and the patient oscilates between two dangers; rapid interference and disturbance of nutrition if elimination be too prompt, and auto-intoxication if the glycose accumulates in the organism. The whole pathology of diabetes is in these two terms. The indications easily follow: they are derived from the pathogency, the cause and the ensemble of symptoms.

The diabetic makes two much sugar; the first attempt of the physician should be to moderate this. Now, clinical experience, as well as experiment, has shown that glycogen is formed in the system nearly exclusively from the amylaceous and saccharine foods. Hence, those foods should be reduced to a minimum which either contain sugar or are capable of being transformed into sugar in the intestine—such as the vegetables containing starch, bread, pastry and fruits. In slight cases an absolute meat diet for a few days will suffice to cause the sugar to disappear from the urine, at least for a time. It is true that the absolute interdiction of starchy foods cannot be maintained for a long time. Man is not a carnivorous animal and, by attempting to feed him on meat alone, one would run the danger of first ruining his appetite and then giving rise to grave disturbances of nutrition. But the art of the clinician consists in carefully combining foods in each particular case, so that the formation of sugar is kept at the lowest possible quantity while general nutrition does not suffer.

Besides diabetic measures, several drugs have the property of moderating the formation of sugar. They are the alkalies and opium. The alkalies, and particularly the bicarbonate of soda, render great service in the light forms, especially in the arthritic variety or that dependent upon a gouty base. This is not surprising if one recalls their efficacy in other diseases of the same family—in rheumatic affections, for example. They appear to act as alternatives. As to opium and its alkaloids, morphine and codeine, these modify, in a certain degree, the formation of sugar in slowing all the operations of nutrition and especially that of the emunctories. Their use is not without inconveniences and they are only to be thought of in serious conditions where the patient no longer assimilates and emaciation is rapid.

The diabetic does not burn up his sugar, consequently there is every day a pure loss of organic material. Therefore favor oxydation as much as possible. In sedentary patients recommend walking or any other physical exercise, as gymnastics, fencing, horseback riding or even bicycling, together with baths followed by rubbing of the skin. But, above all, avoid overdoing, especially in the advanced stage of the disease. In those threatened with acetonemia, substitute inhalations of oxygen. Where it is associated with gouty affections treat also this diathesis. The alkalies, iodides, and sometimes the salicylates, are here indicated. The meat diet is adapted to the typical diabetic, yet where the disease is mixed with arthritism it is prone to be very harmful, especially where the patient is affected with arteriosclerosis and a beginning interstitial nephritis. The clinician will appreciate the weak points and direct his treatment accordingly.

But the patient may also be nervous, neuropathic, either with over-excitement or depression, or these two states follow each other. Nervous excitement will increase glycosuria. Then the bromides or antipyrine are of service if the kidneys are intact. In depressed patients one may employ tonics, cinchona, quinine, the phosphates and arsenic, or, if necessary, the neurasthenic tonics as strychnine or igasurine, which also stimulate digestion. In rapid emaciation administer opium in small doses, advise rest, and those foods which limit tissue consumption. If elimination is deficient and acetonemia menace life give diuretics, order a milk diet and inhalations of oxygen.

Our patient presents a relatively benign form of the disease. He was put upon a test diet. For fifteen days he was advised to eat only meat, eggs, green vegetables, with a half bottle of wine at each meal. At the end of this time no trace of sugar could be discovered in his urine. Hence the prognosis is favorable and an equilibrim will be easily maintained by appropriate hygeine. No sugar nor sweet foods, only three and a half ounces of bread at a meal, but very little of potatoes, but fruits—excepting grapes—will be allowed. As a beverage, wine diluted with an equal quantity of water. To keep him up in nutrition, arsenic in some form, will be prescribed in small doses and for a long time. Exercise to overcome the results of his sedentary occupation; a walk of an hour each evening and morning in the open air. He must report at intervals that his urine may be examined—a precaution necessary in all diabetics, even after an apparent recovery.

The task of the physician is more difficult and complex in those cases which do not yield and the test diet gives no results. Here the patient must live with his affection, and the dyscrasia be kept at bay as long as possible. This is possible if the course be not too acute, and docility and perserverance be manifested on the part of the patient.

From time to time, you have remarked a diabetic patient whom I have cared for for nearly five years and who has been improving steadily since then. He is a man of fifty years, a tavern-keeper by occupation, rather obese and somewhat addicted to alcohol. A short time before I first saw him, he had been for a time in another hospital where he had been upon an exclusive diet of meat and animal fats. Instead of improving he became dyspeptic and his general health greatly suffered. We found him weakened, with nearly no appetite, his tongue red, and as if varnished; he also had frequent vomiting and diarrhœa. His urine was scanty and turbid, not only containing twenty grains of sugar to the litre, but eighty grams of albumen. We discovered manifest signs of generalized arterio-sclerosis with a little cardiac hypertrophy; besides his liver was large and hard. In short, digestion was disturbed and all his emunctories were functionating badly. Neglecting for the moment the glycosuria we tried to increase the urinary secretion and eliminate the toxines contained in the system. We accordingly prescribed a milk diet at the risk of increasing the amount of sugar. In fifteen days the urine was normal in amount, the albuminuria had nearly disappeared and the quantity of sugar was also decreased. At the same time, the digestive functions became normal and his general nutrition greatly improved. The iodide of sodium was prescribed in small doses, five cgms, per diem for ten days of the month; during the remainder he drank wine diluted with an infusion of cherry stems. Every ten days he took a glass of a solution of the sulphate of soda or magnesia as a cholegogue. Twice a year the iodide is replaced by the salicylate of lithine, one gram a day in powders. As to his diet it was never very rigid: eggs, green vegetables, milk porridges. His general nutrition is all that could be wished though he can not give up alcohol entirely. No polyuria nor azoturia. Once or twice during the five years symptoms of auto-intoxication, dyspepsia, diarrhoea, somnolence and great loss of strength have reappeared but a few days of milk diet served to set these aright; this shows that in this typical arthritic patient there is no danger of excess of sugar in the blood but of failure of elimination. The patients of this type are those which one meets with in city practice; patients of middle age or the shady side of life, with a hereditary gouty history, arthritics and often gouty or obese and nearly always affected with more or less pronounced arterio-sclerosis. To try to place them under a strict antidiabetic diet is a mistake for it easily disturbs digestion, with consequent

hepatic and renal congestion. Besides, these patients easily become disgusted and are only too inclined to leave off all treatment if you ask them to do that which they can not. As long as the quantity of sugar remains moderate all you efforts should be directed towards modifying the diathesis: in fat and gouty subjects administer the alkalies and iodides, watch the digestion and the action of the liver, stimulate the circulation and prevent accumulation of waste products. In neuropathic subjects alternate the antispasmodics, valerian, bromides and antipyrine with the reconstituents, arsenics, phosphates, quinine, Peruvian bark and strychnine. Finally, where possible, complete the treatment by employment of an alkaline or arsenical mineral water. All these therapeutic measures so valuable in the benign and prolonged forms will completely fail in malignant diabetes which is not surprising if one admit, with Lancereaux that this form is due to acute atrophy of the pancreas, a destructive lesion probably of infectious origin. Here absolute meat diet will yeild the best results. Roast beef, eggs and fatty foods, as much as the stomach will bear to the exclusion of other foods will be indicated. Sustain the strength with broken doses of quinine and cinchona, to which may be added those agent hindering tissue waste as coffee, cocoa, kola nut, and, in a limited measure, alcohol. If, in spite of this, emaciation is rapid limit it by opium or codeine in elevated and rapidly increased doses. Place the patient in a state of absolute physical and moral repose. We recently had an example of what a pernicious effect fatigue will have in such a case. A man of thirty-two years affected with maligant diabetes had had his disease arrested by treatment and one morning, after a discussion with some of his neighbors he suddenly left the hospital and walked home, a long distance. As soon as he arrived there he went to bed, was attacked almost immediately with diabetic coma and in two days he was dead. Put the patient on his guard, examine the odor of his breath frequently, watch for the first signs of acetonemia and at the first sign of this complication place him on an absolute milk diet, give him inhalations of oxygen and hypodermics of caffeine, the only means of preventing a fatal issue.

TRANSLATIONS.

THERAPEUTICAL SUGGESTIONS FROM FOREIGN JOURNALS.*

ANTIPYRINE IN PAINFUL AFFECTIONS OF THE BLADDER AND PROSTATE.

Dr. Brik (*Hospitals Tidende*, No. 24, 1894,) has obtained very favorable results with antipyrine in painful prostatic and vesicle diseases. In those with prostatic affections the frequent urination especially at night, is decidedly decreased and becomes easier and less painful. He administers the remedy as a rule by the rectum-0.50-2.0, dissolved in sixty grams of warm water. In more obstinate cases he injects twenty to thirty ccms. directly into the bladder itself. Also instillation of ten to twelve drops of a five to twenty per cent. solution into the prostatic part of the urethra by means of Guyon's instillator has yielded him good results in painfulness of this part.

Dr. Vigneron (*Annals des Organes Genito-Urinaires*, May, 1894,) also warmly recommends antipyrine as a local analgesic of the bladder. He employs it especially to prevent pain after injection of solutions of the nitrate of silver and sublimate, in patients with cystitis. He injects ten to twenty grams of a four per cent. solution of antipyrine into the bladder and allows it to remain there for ten minutes before either the nitrate of silver or sublimate solution is injected.

OPIUM IN LARYNGEAL STENOSIS IN CHILDREN.

Dr. Carl Stern (*Therapentic Monatshefte*, May, 1894,) observing that in this disease the dyspnœa is increased by restlessness, mental excitement or anxiety attempted to quiet the nervous system by means of opium. In this manner he has been able to obtain great relief in many cases, and to avoid tracheotomy where it

* In charge of the Translator, F. H. Pritchard, A. M., M. D.

was apparently indicated. His observations were made upon children sent to the Marien Hospital at Dusseldorf, where after treatment in town, they were declared "ripe" for a tracheotomy. The dose was from two to three drops of wine of opium according to the age of the child; children between one and two years require three drops, as a rule. If no results are observed after a half hour he gives two drops more. Naturally enough he does not regard this treatment as a substitute for tracheotomy, for in many cases he finally was obliged to operate, but it is a valuable palliative method.

CARDIAC WEAKNESS IN ARTERIO-SCLEROSIS.

In *Lo Sperimentale*, No. 12, 1894,) the disagreeable palpitation of arterio-sclerosis from cardiac weakness is said to be quite well controlled by the following formula:

℞

Chloral Bromide.....Soda āā	4	o (ʒj.)
Water.....		
Codeine.....		10 (grs.jss.)
Syrup Orange Peal. āā.....	45	o (ʒjss.)

S. A desertspoonful every hour until the heart is quieted.

BELLODONNA AND THE GALVANIC CURRENT IN EPILEPSY.

Prof. E. De Renzi (*Rivista Clinicate Therapeutica*, No. 6, 1894,) in a case of epilepsy, which resisted large and progressive doses of the bromides tried belladonna and gobvanism in a young boy. Not much was expected but the result was surprising. Instead of having attacks every day, especially during the night, of quite an intensity, there followed a few light seizures of short duration during the first days of treatment, and then they ceased entirely. The belladonna was administered as follows:

℞

Alcoholic Extr. Belladonna..... Extra Gentian. q. s. for forty pills	20 (grs.iij.)

S. One pill morning and evening.

The galvanic current was applied for five to fifteen minutes to the spinal column; one pole to the back of the neck and the other to the lumbar region. The electrodes were three to five centimetres in diameter, and the strength of the current from two to six milliamperes. From time to time the current was reversed.

TREATMENT OF CRUSHING INJURIES OF THE EXTREMITIES.

Dr. P. Reclus (*La Semaine Medicale*, No. 41, 1894,) in these forms of injuries employs as an antiseptic salve, the following formula:

℞

Salol		
Resorcine, āā.....	12	o (ʒiij.)
Antipyrine, āā.....	12	o (ʒiij.)
Boric Acid.....	20	o (ʒv.)
Iodoform.....	1	o (grs. xv.)
Vaseline.....	160	o (ʒv.)

After a few whiffs of chloroform to render the patient slightly insensible, the crushed parts are washed with water at 55-60° irrigating with sufficient force to wash out the clots, foreign bodies, dirt, etc., and to reach all the pockets. Then this salve is applied on pieces of sterilized gauze which are tucked into all the crevices, the whole wound is then covered with the salve, and over this absorbent cotton is placed. This dressing is renewed every five to six days. It is advisable to apply either a splint or a plaster of Paris bandage. When the injury has not been too severe one may sometimes, with this treatment, succeed in saving the entire limb. Otherwise amputation may be delayed until partial cicatrization has taken place and a better stump is obtained.

TAPE-WORMS IN CHILDREN.

Dr. Descroirilles (*Rivista Clinicale Therapeutica*, No. 6, 1894,) advises the following method of treating tape-worm, in children:

1. For two or three days keep the child on a preparatory diet; soup from lean meat, eggs, milk, bread in moderation.

2. During the last twenty-four hours, absolute milk diet.

3. The evening before expulsion is attempted give a rectal injection, and a second and abundant one three hours before administering the remedy. His formula is as follows:

℞

Ethereal extr. Male Fern.....	8	o (ʒij.)
Calomel.....		40 (grs. vj.)
Peppermint Water.....	10	o (ʒijss.
Gum Arabic.....	5	o (ʒj ¼)
Simple Syrup.....	20	o ʒv.)
Distilled Water to.....	60	o (ʒij.)

S. To be taken by the spoonful every ten minutes.

5. A few hours after its administration, give a rectal injection of twenty-five to thirty grams (six drahms to an ounce) of castor oil.

He also recommends Duhourcau's method which consists in administering in capsules, the green ethereal extract of male fern with chloroform, castor and croton oil. The chloroform anesthetizes the parasite, the male fern in this form is a tænicide, while these oils act as purga-

tives. He thinks it an ingenious combination which covers all the indications of the condition.

A SALVE FOR ACUTE ARTICULAR RHEUMATISM.

Dr. Fienga (*La Semaine Medicale*, No. 34, 1894,) recommends highly the following formula in the treatment of acute articular rheumatism:

℞

Salicylate Soda	30	o (℥j)
Iodoform	10	o (℥ijss.)
Vaseline	100	o (℥iij. ℥j)
Extr. Hyoscyamus	5	o (℥ij¼.)

The affected joints are rubbed with this salve and then wrapped in cotton; they should be renewed every six to twelve hours. Under the influence of this local treatment and milk diet, without other internal treatment a rapid cure was obtained in all the cases under his care.

TREATMENT OF ECZEMA OF THE EXTERNAL EAR.

Dr. Chatellier (*Revue Internationale de Bibliographie Medicale*, No. 11, 1894,) from an experience of more than six years recommends iodol most highly, in this affection. The vehicle only varies with the form of the disease.

EXUDNG ECZEMA.—In the generalized and confluant form occupying the auricle and retro-auricular fold or situated in the meatus itself as little vesicles such as are sometimes observed after treating suppurative inflammation of the middle ear, by boric acid in powder or dissolved in alcohol, the affected part is washed with Van Swieten's solution, diluted with three or four times its volume of water. Then it is carefully dried with absorbent cotton. The external parts are then dusted and the meatus filled with finely powdered iodol. A pledget of cotton will serve to hold the water in place. Renew this dressing morning and evening until a cure follows.

DRY ECZEMA.—This affects the auricle or the neighboring parts. Treat as in the former form, and instead of dusting with the powder apply the following salve:

℞

Iodol	1	00 (grs. xv.)
Lanoline	30	o (℥j.)

Cover with a layer of cottun.

ECZEMA OF THE CANAL.—Remove the epithelial scales by injecting diluted Van Swieten's solution and dry with absorbent cotton wrapped around the end of a probe. Fill the canal then with:

℞

Iodol	1	o (grs xv.)
Albolene	30	o (℥j.)

Introduce a pledget of cotton to retain it as long as possible. Renew this dressing morning and evening so that the affected parts are always in contact with the remedy. At the end of fifteen days the eczema will be cured. Then wash out the canal well and leave off treatment. Lanoline and albolene are preferred to vaseline, as this latter is often impure and irritating.

CORN SMUT AS AN OXYTOCIC.

Dr. V. Grouzdeff (*La Semaine Medicale*, No. 34, 1894,) in a series of observations made in Prof. Lebedeff's obsterical clinic in St. Petersburg on eight parturient women with uterine inertia, comes to the conclusion that corn smut is an efficient oxytocic. He claims it to be devoid of the inconveniences of ergot and indicated at all stages of labor, with insufficient contractions of the uterus. He employed a tincture of the drug and in doses of two to four grams (gtts, xxx ℥j.) In all of his cases except one where there was no result, strong and regular pains appeared, in twenty-five to forty-five minutes. It produced neither tetanic contractions nor nausea nor vomiting. Other means as quinine, alcohol, baths, etc., had been first tried in all these cases before the remedy was given.

CHRONIC ARSENICISM.

Drs. Gaucher and Barber (*Gazzetta Degli Ospedali*, No. 78, 1894,) presented a case of chronic arsenic poisoning before the French Dermatological Society recently. The patient had a number of cicatrices from ulcerations upon the scrotum, palmar and plantar keratosis, a perforation of the nasal septum, a decrease in the quantity of urine and other signs of interstitial nephritis. His hands were the seat of a pronounced sclero-dactalia. They regard all these symptoms of chronic poisoning by arsenic as of central origin, and as a trophoneurosis independent of vascular sclerosis.

EDITORIAL.

"CURING" INEBRIETY.

Only of recent years has science recognized inebriety to be a veritable disease. If the former conviction that inebriety was exclusively a vice is an error, equally erroneous is the belief of extreme reaction that inebriety is exclusively a disease. The truth lies between these extremes. Inebriety is at once a disease and a vice, and appears as either, according as the one or the other characteristic may predominate. It may exist as a disease with the vicious element entirely wanting; as in the case of an individual whose inherited mental and physical tendencies toward alcoholism are utterly out of proportion to his personal power of resistance when such tendencies have been allowed a single opportunity to gain ascendency. In this phase inebriety is a morbid condition—dipsomania,—and is characterized by the irresistable obsession and impulse to drink, recurring as periods during which the victim abandons himself absolutely to the thirst for alcohol. Between attacks the unfortunate patient may be totally abstinent; may appear perfectly rational, and may be able to conduct all the ordinary affairs of life without evincing any unsoundness of mind. He may even make most heroic but ineffectual effort to resist the recurring impulse to drink. Such an one is undoubtedly diseased rather than vicious. The dipsomaniac invariably belongs to the degenerate class which is characterized by the so-called psychopathic constitution. His physical make-up is always imperfect and his mental and moral balance is never stable.

On the other hand inebriety may be essentially a vice, at least in so far as it may have been acquired and for some time continued as a vice. Thus an individual in whom hereditary tendencies are not pronounced, or are entirely wanting, may acquire the drink habit willfully. Inebriety begun as the vice, if continued, invariably terminates as the disease.

But whether vice or disease, a remedy has always been sought for. So long as it was considered as vice simply, the only remedies indicated were such as are regarded available for moral obliquities. When inebriety was recognized as a dis-

ease physical as well as mental and moral, relief was demanded at the hands of the medical profession, and, pending the further study and investigation of the disease with view to obtaining a rational mode of treatment, an opportunity is afforded charletans to grow rich by taking advantage of the hopes and credulity of the long suffering public. This opportunity has not been neglected and the field is already overflowing with nostrum-boomers.

A nostrum is a fraud wherewith fakirs fleece fools. No matter how greatly nostrums may vary in other respects, all bear the long-ear-marks peculiar to the species—characteristics indeed which define the class. Briefly mentioned these distinctive pecularities, which are always offensively prominent, are: (*a*) A marvelous discovery, either as the crowning result of a life-long effort to better the condition of man, or as a special revelation to a devoted philanthropist, or, perchance, an observation accidentally made during some profound scientific research in another direction. (*b*) A secret to be preserved at all hazards: a mystery so unfathomable as to cape the deepest investigation of modern scientific precision. The power is so potent that only the initiated can safely exercise it, and knowledge of it allowed to the general would bring untold devastation on humanity. (*c*) It is cordially condemned by the science which cannot appreciate it, and is reprobated by a bigoted medical profession which decries any departure from the ruts in which it runs. It is foolishness to the Greek and to the Jew a stumbling block. (*d*) It is an infallible specific for diseases that have hitherto been regarded incurable. This may be proved by testimonials from innumerable grateful ones, who, after years of illness and suffering all things at the hands of many physicians, have been cured by taking an indefinite amount of the specific, and are now rejoicing in absolutely perfect health, etc. (*e*) This mysterious power, so providentially revealed to some hitherto obscure but worthy lover of his fellowmen, despite the ridicule and opposition of jealous and envious self-seekers, will be most generously and faithfully used for the healing of the nations by the self-sacrificing trustee—for a consideration.

These characteristics never occur coincidentally save in a nostrum. And through them a nostrum should be as evident to the most credulous as it is to thoughtful educated people. *Verbum sat.*

All the so-called "cures" for inebriety present the above characteristics, but one cure in particular has been manipulated so skillfully that its notoriety has become universal and it has developed into a commercial factor of some prominence. The reference is made to the "Bi-chloride of Gold Cure."

Without entering into any discussion of this particular business undertaking, we append on editorial from the *Christian Advocate*, of New York, remarking that we are pleased to see this effort to obtain and make general information valuable to the public. Medical men are now beginning to obtain statistics of the results of the "Gold Cure," which will undoubtedly confirm the correctness of the first estimate of the enterprise, which was reached by the application of general principles. But the public-at-large need reliable information from sources other than professional. Religious papers are preferred advertising media for nostrum venders, and credulous or careless clergymen are the endorsers most sedulously cultivated by charletans. And most persistently has the influence of the clergy and of religious bodies been sought, obtained and paraded by the philanthropic institution in question. It is therefore most refreshing to find a religious paper, perhaps the most influential in America, with widespread sources of reliable information and much wider opportunities for disseminating it, without pre-

judice or bias undertake the work proposed:

"The public has often been assured that ninety-five per cent. of all the KEELEY graduates are "cured" or "reformed," and that the relapses are few. We know of the KEELEY "graduates" that we have met four have relapsed, two have committed suicide, and others are in asylums, making more than fifty per cent. of the small number that we chance to know.

"Though we do not doubt that a considerable number have not been intoxicated nor used intoxicating liquors in any way since they left the KEELEY Institutes, we do not believe that the representations attributed to the agents and managers of the said institutes are to be received without an uncertain but large discount. It is difficult to obtain accurate and impartial statistics, but we will attempt it with the cooperation of our readers, and herewith submit a plan.

"So far as we can ascertain at least seven thousand *Ministers* and fifteen hundred *Physicians* are numbered among our subscribers, though some of the latter, whose papers are addressed "Doctor," may be *Dentists*. They are scattered over the United States and in foreign countries. The number of persons who have been inmates of the different KEELEY institutions is large, and they come from all sections. Our plan of ascertaining the results requires co-operation from ministers and physicians, a little thought, and a willingness to take the pains to send us a letter or postal answering questions which are herewith submitted.

"Before stating the questions explanations are necessary.

Many drunkards are periodical; they have often passed three, six or even nine months without tasting ardent spirits or anything that can intoxicate. Suddenly they start upon a terrible spree which becomes known to their friends, and usually to the public. After this subsides they go on as before till another outbreak.

"Others are sots, drinking themselves stupid or helpless nearly every day in the year, many able to attend to business in the morning, but not to be seen for such purpose after four or five o'clock. Some are regular drinkers, ordinarily drinking but little, but combining therewith the periodical characteristics.

"In view of these facts, should a *periodical* drunkard [or dipsomaniac, methomaniac, or oinomaniac] enter a "KEELEY cure," and remain sober for six months afterward—if he had been in the habit of being sober for long intervals between his sprees—no proof of his reformation in any proper sense could be adduced from his keeping sober for a few months after the treatment. We think that *nine* months is the shortest time that can reflect light on the question of *cure*;—though a less period, unless some evil results in other respects occur, may indicate the value of the treatment as an *alleviation*. Our questions, therefore, addressed exclusively to ministers and physicians, are the following:

"1. How many do you *know* who have taken the KEELEY treatment?

"2. Of those who have taken it, how many, *to the best of your knowledge and belief*, have remained *sober and totally abstinent* for a period of *nine* months or more?

"3. How many have *relapsed* in less than that time or have committed suicide, or become insane, or have been physically seriously injured by the treatment?

"Except in the case of *personal acquaintance*, we do not ask for information from subscribers in general because we would have no way of preventing the duplication of returns. By confining it to ministers and physicians we get one or two persons in a locality, and can correspond with them as to whether they have duplicated.

"We wish no information from *agents* or *managers* of "KEELEY cures" or *graduates* thereof. The former are expected because of their business interests: the latter, because in that case we should get repeated information from the same locality. Neither do we wish mere heresay information from ministers or physicians. If A tells B that he knows C; that C was a drunkard and was cured by a KEELEY institute, and has never touched a drop of liquor since, and B tells us about it, it is of no value in this case. Nor do we wish *names*, but on the honor of a minister or physician we merely wish, as stated above, the number that he knows to have taken the KEELEY cure, and what were the results. Nor do we wish this inquiry to be confused with any other "cure." Since Dr. KEELEY began to be noted and to make vast profits, scores of imitators have sprung up, as is always the case; and he has a number of times declared that his institutes have been traduced by the fact that other graduates, who have lapsed, have been charged to them. We will tabulate and publish the returns"

Uræmia.

Dr. L. D. Kastenbine highly recommends:

℞

Tinct. ferri chloridi	℥ss
Spiritus ætheris nitrosi	
Lid. ammon. acetatis	āā ℥j.
Aquæ destillatæ	℥iiss.

M. et fiat mistura.

Sig.: Tablespoonful in a wineglass of water.

—*Louisville Medical Monthly.*

Torsion of Arteries for the Arrest of Hemorrhage.

Doctor Claude A. Dundore, of Philadelphia, in an interesting paper describes this method and credits Amusat with first having observed the effect of arteries in arresting hemorrhage.

He has used torsion in 113 cases of all kinds with no signs of secondary hemorrhage, and with fewer cases of delayed tissue unions. He thinks that if the vessel is dieased that torsion is safer than the ligature, which very often, even when little force is exerted in tying, partially or entirely severe the external coat, thus by hastening the sloughing of the end of the vessel, tending to produce secondary hemorrhage. In cases of diseased vessels, the limited method of torsion should only be used, and the end of the artery should not be rotated more than twice.

In plastic operations the fact that we are enabled to close the wound without leaving a loop of catgut to irritate or produce sepsis and delay union, is an advantage which cannot be to highly appreciated.

Doctor D. ends his paper by stating that he is satisfied that those who will give torsion their practical attention will be amply repaid and thoroughly convinced that as an agent for the averting of hemorrhage it is the equal if not the superior of the ligature in many respects. —*International Med. Mag.*

ABSTRACTS.

DIAGNOSIS IN PÆDIATRICS.

The Dublin *Jour. of Med. Sc.* points out that the complexion may be clear and delicately tinted, though pallid, as in the tubercular. If cyanosed, it suggests a respiratroy cause; a leaden or earthy tint, especially with great pallor about the upper lip; will frequently be found with gastro-intestinal trouble; the swarthy (*café au lait*), though pallid, face may put the physician on his guard for syphilis; in the spasmodic stage of whooping-cough the face becomes swollen, often ecchymosed, the eyelids puffy, the conjunctiva conjested and bloodshot; the sunken, vacant eyes, with dark areola around them, indicate great collapse. The expression of the face will not infrequently indicate even the seat of the disease. Jadelot has pointed out the following lines in the infant face which, by their position, indicate the seat of derangement: The oculo-zygomatic line from the inner canthus of eye downward and outward to the cheek, a little below the malar eminence, pointing to derangement of the brain and nervous system. The nasal line, from the upper part of the ala nasi. curving downward around the corner of the mouth; said to be never absent in gastro-intestinal derangement. The labial line, beginning at the angle of the mouth and running downward and outward, generally accompanied by rapidly-moving nares; a fairly trustworthy sign of diseases of the lungs and air-passages. The child's attitude should also engage attention. A healthy infant lies with limbs semiflexed, and, if on his back, inclines one cheek to rest on the pillow. When the limbs and trunk are rigidly stretched out, tetanus is suggested; when unconscious, or in great weakness and prostration, the child will be found lying flaccid on his back, with face to ceiling. If found on his side, curled up and with head retracted, a frown will probably be seen, together with the oculo-zygomatic line, suggesting cerebral irritation, or, if there is opisthotonos, spinal irritation. If there is intolerance of light, as in cerebral irritation, the face will be buried in bed-clothes. In abdominal discomfort or in rickets, the child presistently lies on his face, or even rests on elbows and knees. As regards the cry, some information may also be gained here. Sharp, violent fits of crying, with vigorous movements of the legs, usually indicate colic; the sudden, sharp, single, piercing cry uttered at intervals, while the patient lies in a stupid drowsy, semi-unconscious state, is but too suggestive of meningitis; while the hoarse grating cry of syphilis is characteristic. In contrast to these, note when the child does not cry, as in profound weakness brought on by diarrhœa, and in grave pulmonary affections where the breath is too precious. Lastly, both suction and deglutition, should be noted. Dyspnœa and acute fever cause suction to be performed in short snatches; syphilis also necessitates pauses for breathing. In thrush or ulceration, suction and deglutition are evidently performed with great pain; if the throat be sore, there is frequent cough and noise in deglutition. In great prostration, if the child swallow at all, it is an exceedingly hopeful sign.

Antidote to Potassium Cyanide.

J. Kossa (*Vratch*), considering that potassium permanganate ought, theoretically, to act as a chemical antidote to potassium cyanide, has performed experiments, the results of which appear to fully justify his hypothesis. Rabbits were shown to be fatally affected in a few minutes by .01 gramme of the poison, but if, at the time of administration, .5 gramme of permanganate dissolved in fifty cubic centimetres of water was also introduced into the stomach, doses of cyanide up to .1 gramme failed to cause death. Larger quantities (.2 gramme) proved fatal under similar conditions, but the action of the poison was much delayed. Successful experiments were also performed with aqueous solutions of hydrocyanic acid containing .1 per cent. It is suggested, therefore, that in cases of cyanide-poisoning one-half to one-third litre of a three to five per cent. solution of permanganate be administered immediately. — *Druggist's Circular and Chemical Gazette.*

TREATMENT OF FUNCTIONAL DYSPEPSIA.

Dr. R. C. M. Page states that, in any case, meals should be regular, and the food eaten with deliberation instead of being swallowed hurriedly, especially while mentally worried about some scheme or other. In atonic dyspepsia, as a rule, tonic treatment is indicated and the patient has to be built up. But in irritative dyspepsia the very opposite course is often to be pursued, care being taken especially to avoid starchy and fried foods and fats, as well as alcoholics, Besides removing the cause and regulating the diet, many remedies have been suggested. Of these he recommends papoid as one of the best. It dissolves abnormal mucous secretions, thus removing a prime cause of fermentation besides stripping the food of its mucous envelope and thus exposing it to the action of the gastric juice. In addition to its direct digestive action on the stomach's contents, it seems to have a stimulating effect upon the gastric mucous membrane. Its therapy is not materially interfered with by any of the drugs usually given internally and it is equally efficacious in acid, alkaline, or neutral media. That it is not destroyed in the stomach, like animal pepsin, is shown by the fact that even in ordinary doses a trace of it may be found in the stools, thus showing that the whole gastro-intestinal tract has received the benefit of its action. Where diminished peristalsis is marked accompanied by accumulation of gas in the stomach and bowels, it is well to add strychnine. The average dose of papoid is about one and a half to three grains thrice daily after meals, and one of the most convenient methods for its administration is in tablet form. With papoid other remedies may be used. One of the best is the rhubarb and soda mixture with tincture nux vomica, or if the case be due to abuse of alcohol (rum stomach), tincture capsicum should be added. where palpitation and irregular heart's action are present tincture digitalis may be added to the same mixture (℞. Tinct. digitalis ʒi., pulv. rhei, pulv. sodii bicarb. aa. ℈ ii, aquae q. s. ad. ʒxvi, m. sig. ʒi ter die). Washing out the stomach by means of the stomach tube was once in vogue, but now it is chiefly where dilatation is marked as in obstruction to the pylorus from cancer or other cause. Besides actual treatment, patients who can afford it often improve, or are perfectly cured, by taking a course at some watering-place, care being taken to make a proper selection, which can only be done by advice of some physician who is intelligent on such subjects.

CARE OF THE MOUTH IN SICK PERSONS.

Rosenback (*Zeit. fur Krankenpflege,*) says that in many illnesses there is almost sure to be secondary trouble in the mouth if preventive measures be not taken. A warning sign is dryness and redness of the tongue and mucous membrane of the mouth, with difficulty in swallowing; further signs are an evil odour from the mouth, coated tongue and gums, bleeding of the gums, etc. Just as care of the mouth is required in patients with carious teeth, smokers and chewers of tobacco, so it is also in the case of unconscious or paralysed persons; patients with fever or suffering from chronic digestive complaints; those taking medicines, such as mercury or iodides, or who, on account of general weakness, have to take strong alcholic drinks; but, perhaps, the most important class of those in whom special care of the mouth must be taken are patients with fever. Parasites are always present in the mouth, but it is only when the tissues are weakened that they undergo invasion by these parasites, which become then really pathogenic. There is nothing which one can do for sick persons which is unimportant, and by neglect in the care of the mouth convalescence may be retarded. Rosenbach concludes with the following rules: (1) Patients with good digestive powers, free from fever, and with no loss of consciousness require no more than the ordinary care of the mouth. (2) In children and very old patients the less solid food taken the greater should be the care with

the mouth. They should rinse the mouth out several times a day with lukewarm water containing a little common salt, tincture of myrrh or eau-de-Cologne added to stimulate secretion. When there is a tendency to bleeding of the gums or when the teeth are bad a pinch of powdered boric acid may be twice daily rubbed in between the lips and gums. Patients with false teeth should remove their false teeth when, owing to loss of appetite or chronic gastric disturbance, they cannot take solid food. (3) In patients with partial loss of consciousness the mouth should be examined several times a day for small sores, such as may arise from the pressure of the teeth on the lips, etc. Such sores should be powdered with a little boric acid or chlorate of potash, and the cracks at the corners of the lips heal quickly if dried with a clean towel and treated with boric acid or vaseline. The mucous membrane may be stimulated by wiping the tongue and mouth and pressing on the tongue with a moist towel every two or three hours; if necessary, the hinder part of the tongue should be cleaned with a wad of cotton wool fastened to a stem. If the patient sleep with the mouth open the air in the room must be kept moist; a moistened layer of muslin laid on the mouth may be of some service. (4) Patients with fever should have something to drink—cold water or weak lemonade—at least every hour; one must not wait until the patient asks for a drink. Besides preventing dryness, the fluid maintains the activity of the glands and the whole function of the mucous membrane. Many patients are prevented from drinking by a painful, dry and cracked condition of the lips, and therefore all feverish patients should from the commencement of their illness have their lips rubbed several times a day with vaseline or fat. In protracted cases of fever the mouth may also be swabbed out with oil, fat or greatly diluted glycerine.—*British Med. Journal.*

OXALURIA.

Boursier (*Ann. de la Soc d' Hydr. Med. de Paris*, 1894) gives notes of 66 cases treated at Contrexéville. Oxalate of lime is probably intimately allied to uric acid, and out of 450 patients suffering from gout or uric acid gravel Boursier found crystals of oxalate of lime in the urine of 150. Debout d'Estrees found it slightly less frequently. The high specific gravity, usual in the urine of oxaluria, is probably due to the presence of oxalates, and when these are replaced by uric acid the specific gravity of the urine usually falls. The renal pains in oxaluria vary much in intensity and situation; they may be accompanied by nausea, and take on the appearance of true nephritic colic, with or without the expulsion of oxalic gravel, but the intensity of the pain is in no relation to the size of the oxalic fragments. Hæmaturia was observed in more than a third of the 66 cases; it is usually very slight, and results, not from the presence of oxalic gravel, but from congestion of the kidneys due to the irritation by the oxalates. In one case hæmoglobinuria, like paroxysmal hæmoglobinuria, was observed. In oxaluria the bladder may be irritable, and the frequency of micturition, accompanied by intermittence in the stream and a sensation of burning in the urethra, may give rise to a suspicion of vesical calculus. Oxaluria may be, so to speak, physiological, that is, due to a diet with vegetables rich in oxalate of lime, or it may be pathological. In the latter case it forms part of a "syndroma" of symptoms, the chief of which are dyspepsia and nervous troubles. Dyspepsia was noted in half of the 66 cases; constipation was also frequent and often accompanied by hæmorrhoids; diarrhœa was noted in some cases. Owing to their nervous troubles many of the patients may be classed as neurasthenics. Boils and carbuncles frequently accompany oxaluria. Boursier has not noticed the spasmodic cough recorded by some English authors. In the etiology of oxaluria heredity plays a great part, especially hereditary predisposition to arthritism. As determining causes Boursier attaches most importance to dyspepsia and nervous troubles; he considers that oxaluria should be regarded rather as a form of dyspepsia than as a separate disease; he does not, like Begbie, think that the dyspepsia and nervous troubles are due to a sort of "oxalæmia."

Boursier follows Hahn and Beneke in attributing oxaluria to an arrest in the catabolic changes normally undergone by nitrogenous material before excretion from the body; hence it is that oxaluria is induced by all the causes which lead to a disturbance in nutrition, the *ralentissement de la nutrition* of Bouchard, which prevents the proper oxidation in the tissues. Oxaluria may lead to the formation of oxalic gravel or calculus in the kidney or the bladder; these differ from those of uric acid, because in the case of oxalate of lime the frequency and intensity of nephritic colic are in general greater and hæmaturia is more frequent; another difference is that uric acid sand is more often expelled than oxalic sand. Oxalic calculi take longer to form than those of uric acid, and therefore relapses after their removal are less frequently observed. Treatment with Contrexeville water is better at the place itself than at home. More than eight glasses—about 2½ litres—a day is not recommended. To complete the treatment at Contrexeville it is sometimes advisable to continue taking the water at home.

SPECIFIC DIRECTIONS FOR USING WATER IN NERVOUS DISEASES.

Dr. F. Peterson (*American Journal of the Medical Science*) says:

Anæsthesia (cutaneous.—Short cold jet and fan douches of strong pressure to the anæsthetic areas. Temperature, 50° to 70°. Duration, one minute. Daily.

Angio-paralytic hyperidrosis of the feet.—Prolonged cold foot-bath with chafing, or fan douche of cold water to the feet. Temperature, 60°. Duration, twenty minutes for bath, five minutes for douche.

Chorea—Cold plunge beginning at 90°, daily reducing until 70° is reached. If anæmic, spinal spray, jet or fan douches, at first warm until patient becomes accustomed to them, then gradually reduced to 60° or 50° (Duval.)

Epilepsy.—Cold shower baths and cold sponge baths daily are beneficial. The shower baths should be rain-like in character—that is not too forcible. In many cases a morning and evening bath (the "half bath") proves very serviceable. The "half bath" is taken in a bath-tub only half filled with water, and when taken should be accompanied by energetic rubbing of the patients by an attendant. This bath lasts five minutes, and the temperature should not be under 50° and not over 70° F. Where there is evidence of hyperæmia and increased blood-pressure in the head, the cold cap is useful.

While these are the general indications for hydrotheraphy, certain measures are often of use at the time of seizures. During a fit or during a *status epilepticus* it will be observed that there is one of two vascular conditions present: either the face is pale and there are signs of brain anæmia, and in this case warm wet compresses should be applied to the head and genitals, accompanied by friction of the trunk upward, the body being placed with head low and arms uplifted; or there is turgescence of vessels in the head, the face is red, the carotids beat strongly, and under such conditions a contrary procedure is indicated—cold compresses to the head, neck and genitals, strong wet beating of the feet, with a high position of the head. Daily applications for thirty seconds.

Headaches, neuralgias and migraines.—If anæmia, heating cophalic compresses (wring out thin linen bandages in very cold water; wrap head in capelline manner, and cover with one or two layers of dry linen or flannel.) Apply at bed-time. Upon removal, envelop head in dry cloth and rub it dry. If hyperæmic, leg bandages (a piece of toweling a yard long is dipped in cold water at one end—one third—thoroughly wrung out, and wrapped closely about each leg, so that the wet surface is next the skin and the dry portion envelops the wet two or three times; or wet stocking may be put on and covered with dry towels.) These are applied at bed-time and retained through the night. In many headaches, especially of a congestive character, a prolonged cold foot-bath (twenty minutes, 60°) or the fan douche to the feet (five minutes 60°) is very palliative.

Hysteria.—For erethetic type: Wet pack, 60° to 70°, for one hour or more, followed by massage (Putnam Jacobi;) or the rain-bath at 75° to 65° for thirty-five seconds daily at twenty pounds pressure (Baruch.)

SOCIETY REPORTS.

THE AMERICAN CLIMATOLOGICAL ASSOCIATION.—ELEVENTH ANNUAL MEETING.

Washington, May 29–June 1, 1894.

Dr. Andrew H. Smith, New York, President of the Association, after a brief introductory address, read a paper on

ALIMENTATION IN PULMONARY DISEASE.

The problem of alimentation, in pulmonary affections, is complicated by special conditions growing out of the functions of the affected organs. We are too apt to regard nutrition as if it were only another term for digestion, and practically to assume that, if the food taken into the stomach goes through the proper changes in the alimentary canal, and the nutritive portion is properly taken into the blood, that is all with which we need have concern. The products of digestion when received into the circulation are not blood. They represent neither serum nor corpuscles; they are, in fact, dead matter, requiring to be vitalized by the process of assimilation before they become a part of the living blood.

Though we know almost nothing of the manner in which this change takes place, we do know that an essential factor is the process of oxygenation which takes place in the lungs. Material which has not undergone this change is, for the time being, not only useless to the economy, but a hindrance to proper metabolism.

If, then, a considerable obstruction exists to the entrance of air to the lungs, it follows that an addition of more nutritive material in the blood than can be acted upon under the circumstances of crippled respiration, will only add to the circulatory embarrassment and aggravate the condition.

Under these circumstances, therefore, we should study in acute cases to give as little nourishment as will sustain the vital powers, rather than as much as the stomach can be made to digest.

If we pass to chronic affections of the lungs, the same principle will hold good, with certain important modifications in practice. We have a chronic condition in which we are confronted with a restricted hæmatosis on the one hand and urgent necessity for a high degree of nutrition on the other. The difficulty of reconciling these two conditions will be in proportion to the degree of lung insufficiency.

In the minor degrees of chronic lung insufficiency the respiratory movements make up in frequency what they lack in amplitude. But sooner or later a time comes when the respiration is so far impaired that enough oxygen cannot be taken into the blood to act upon such an amount of nutritive material as is necessary for the full maintenance of the economy. The moment this stage is reached, the appetite fails in proportion to the defect in hæmatosis. Unless we can improve the hæmatosis, and with it the whole process of metabolism, we shall only do harm by high feeding. Digestion in these cases fails as well as assimilation. Moreover, in these chronic cases with pronounced anæmia and emaciation, we cannot rely chiefly upon nitrogenous food, as we must do in acute affections of the lungs. The heat producing hydrates and fats are required in addition, and these are more difficult of assimilation. A vicious circle is established, the defective hæmatosis aggravating the dyspepsia, and this in turn resulting in greater poverty of the blood. Under these conditions, life in the open air is of the utmost importance.

The speaker has obtained much benefit in cases of this kind from rectal injections of defibrinated blood. This material seems to be absorbed almost unchanged, the corpuscles as well as the serum; it being a frequent experience that no trace of blood is found in the next dejection. There being no digestive action upon the blood,

its absorption into the venous circulation is almost equivalent to transfusion very slowly performed; and but little change in the way of hæmatosis is required to fit the added material for the immediate use of the tissues.

Dr. Smith described a case of pythisis treated in this way. There was an enormous cavity at the summit of the right lung; the patient was emaciated to the last degree, weighing only 101 pounds. After two weeks of the treatment with blood enemata, he gained seven pounds. At the end of three months he left the hospital; the cavity of the lung had contracted greatly; expectoration had nearly ceased; he had gained 33 pounds.

DR. SMITH said: Though defibrinated blood is preferable for this purpose, good results may be obtained with the materials usually employed for rectal feeding, provided the patient can live much in the open air.

DR. KARL VON RUCK referred to twenty or thirty cases in which he had used defibrinated blood, carefully observing the blood condition of the patients. In one case the percentage of hæmoglobin increased from fifty to over one hundred, the number of red blood corpuscles from 3,300,000 to five millions and over.

In a paper on

THE RELATION WHICH ALIMENTATION SHOULD BEAR TO OXYGENATION IN LUNG DISEASES

DR. BOARDMAN REED, of Atlanic City, concurred fully in the opinion of Dr. Smith, that any excess of food beyond the amount which can be perfectly digested and assimilated is injurious. When the intake of oxygen is large, as in the case of a robust person exercising actively in the open air, a maximum amount of food can be safely given. When, on the other hand, a patient has one or even both lungs crippled, the amount of food which he can digest and thoroughly oxidize into a nutritive pabulum for the use of the economy is much less. Between these two extremes are found patients with all possible degrees of capacity and opportunity for absorbing oxygen, and in consequences equally varying degrees for digesting and assimilating food. Evidently, then, there is such a ratio as has been assumed.

Dr. Reed gave a full report of six cases, four of which are now either well or convalescent, concerning which he says: The results are considerably better than when it was my practice to encourage the fullest feeding of consumptive patients. They have been obtained with the aid of so little internal medicine, and that addressed almost exclusively to the digestive tract, that the management of the diet and hygienic regimen generally should receive the credit.

In the treatment of pythisis pulmonalis, it is of paramount importance to look closely to the blood-making processes by securing as perfect digestion as possible, together with a complete oxidation of its products, so as to spare the lungs from the injurious task of assisting in the excretion of the poisonous compound resulting from suboxidation and decomposition. To obtain these ends satisfactorily, the total amount of aliment ingested must not be in excess relatively to the amount of oxygen absorbed. Dr. Reed considered the importance of selecting a special climate for such diseases greatly over-estimated.

The substance of the paper by DR. GLENTWORTH BUTLER on

THE METHODS AND VALUE OF SUPERVISED EXERCISE IN THE PROPHYNAXIS OF PULMONARY PHTHISIS,

was as follows:

Pulmonary tuberculosis is essentially a disease of defective nutrition. Although of microbian origin, a certain vulnerability of the tissues precedes and underlies the bacillary growth. The same individual may be at one time vulnerable, at another time invulnerable, as shown by the onset and arrest of the disease. The therapeutics of this disease demands that every possible means be employed to strengthen the resisting power of the tissues. Aside from measures designed to prevent tuberculous infection, these means may be thus enumerated; climate; abode and out door life; medication, general and local; personal hygiene and habits of life; diet; exercise, general and local, with its corollary, rest.

For the pretuberculous status and incipient cases, one of the valuable resources for permanently increasing vital capacity is "pulmonary gymnastics." The appreciably best method of taking such ex-

ercise is under the instruction and supervision of a trained operator, acting under general directions from the physician. This method admits of beginning with the gentlest exercise and progressing to the severest, in accordance to the patient's varying condition. It ensures the patient's attendance and economizes the physician's time. Graduates of physical culture schools, qualified to give this training, can be found in all of the larger and most of the smaller towns and cities.

The paper embraced a detailed discussion of the physiologic effects and relative advantages of the use of compressed air, breathing tubes, and voluntary exercise, with a report of cases, and a series of photographs from the living model.

Dr. E. O. Otis, in the discussion following, said: What we need especially to impress upon the physician who treats pulmonary tuberculosis is a study of modern gymnastic methods, and the fact that they are now established upon as careful and as scientific a basis as is the use of any of our drugs. The practitioner who treats any considerable number of cases of phthisis is bound to study the application of chest gymnastics as he would the effect of any drug he uses.

On the second day of the meeting Dr. Vincent Y. Bowditch gave a report of

THREE YEARS' EXPERIENCE IN THE SANITARIUM TREATMENT OF PULMONARY DISEASE, NEAR BOSTON.

He reported twenty-five per cent. of arrested cases and thirty-three per cent. of improved cases.

Dr. Karl Von Ruck made a plea in favor of institution management of these cases. He believed that the ordinary method of sending a patient to a distant climatic resort, leaving him there to consult a physician only when he thought best, which was usually when he suffered a relapse, under no regular treatment, dependent entirely upon the beneficial climate, to the utter exclusion of all other aids, was bad.

Dr. John H. Musser, Philadelphia, protested against the organization of institutions for the treatment of consumptives, within city limits.

Dr. R. G. Curtin, Philadelphia, in a paper on

CREOSOTE, GUAIACOL, AND BENZOYL OF GUAIACOL IN PHTHISIS

gave a brief résumé of observations in the use of these drugs, covering a period of fifteen years.

He said: "In acute catarrhal phthisis with high temperature, little or no good is to be expected from the use of guaiacol in acute tuberculosis, no material benefits results from its employment. The class of cases that seem to be most benefited is the one in which we have slight elevation of temperature, with poor nutrition, slow digestion with fermentation. Guaiacol has no specific effect upon the bacillus. In cases where the process was slow, beneficial results followed the use of guaiacol."

Dr. Curtin's conclusions were as follows:

Guaiacol is not so irritating to the stomach as creosote. Guaiacol is not so liable to produce irritation of the kidneys, nor to be followed by hæmaturia.

Among the advantages of guaiacol are: first, it is more easily taken; second, the process of manufacture insures purity; third, the exact quantity of medicinal substance administered is known.

In the ensuing discussion, Dr. Alfred L. Loomis, New York, said: I do not believe these drugs have any effect upon the pulmonary disease, except so far as they improve the nutrition of the patient by facilitating his digestion. I am quite sure they have no specific action. I have constantly patients coming to me, fully under the influence of this drug, so the odor can be detected in the breath and perspiration, who seem to do just as well without it, and, in some instances, better, on account of its prolonged use disturbing the stomach. Whether we shall gain something by the use of the vapor, seems to me still unsettled. We cannot use it hypodermically. We find no evidence that it has any other effect than to aid assimilation and digestion in a certain class of individuals.

"SHALL ANYTHING BE DONE BY LEGAL AUTHORITY TO PREVENT THE SPREAD OF TUBERCULOSIS?"

Dr. Frederick I. Knight, of Boston, under this heading, called attention to the fact that though twelve years had elapsed since the infectiousness of tuberculosis was established beyond question, very little

had been done to prevent its spread. This was attributed by Dr. Knight not to a want of belief in the infectious nature of the disease, but to the magnitude of the problem and manifest difficulties in dealing with it. Dr. Knight claimed, however, that boards of health were organized to keep people informed, and not in ignorance of dangers in their midst, and gave notice that in the business meeting he should introduce a resolution calling upon this subject.

The discussion of this address was of much interest. Regret was repeatedly expressed as to the present constitution of boards of health in this country and their association with politics. The Massachusetts Board was referred to as being exceptionally fortunate in its chairman.

The resolution offered by Dr. Knight was unanimously adopted. It was as follows:

Whereas, the American Climatological Association was founded, among other objects, to promote the study of the nature and treatment of diseases of the respiratory organs; and *whereas* tuberculosis is the most fatal cause of such diseases; and *whereas* modern research has placed this disease among the communicable, and hence to some extent, at least, among the preventable diseases:

RESOLVED, that this Association do strongly recommend the medical profession of this country to promote measures tending to its prevention.

The objection that is so often made on the part of the people, and also on the part of practitioners, that the dissemination of the knowledge of the infectiousness of tuberculosis stamps the consumptive as an outcast is irrelevant, and it does not hold good. The people are well aware that the patient is not responsible for his disease; and the feeling of sympathy for the consumptive would overmatch any feeling of terror or depression that the people might have for him.

A paper on

SOME PATHOLOGICAL CONDITIONS OF THE HEART AND THEIR RELATION TO DIABETIC COMA

was read by DR. LEONARD WEBER, of New York.

He said that among the sixty cases of diabetes mellitus which he had treated in the course of his practice, he has seen a number die in coma. It is true that the majority of these were the well-known forms of diabetic coma brought about by acid intoxication of the blood, as it is supposed, by acetone and, especially, diabetic acid, but in addition also through the poisonous effects of ptomaines produced by the putrefactive processes so frequently occurring in the alimentary canal of diabetic patients; but quite a number go into collapse through deficient cardiac action, by disease of the heart developing in the course of diabetes, as already pointed out by Frerichs. In these cases there are generally no turbulent symptoms, but syncope followed by cardiac death. They might properly be named collapse-coma, as distinguished from the more frequent forms by blood poisoning. The causes of neuro-muscular disease of the heart in diabetes are manifold.

In the management of diabetes Dr. Weber believes it to be good practice to allow the patient a certain daily amount of carbohydrates as soon as the disease has been gotten under control, and has found this amount to be about three ounces. An absolute meat diet cannot be maintained very long on account of disturbing digestion, and placing the patient in danger of coma.

Every case of diabetes is to be investigated and studied by itself, and the treatment and management adapted to individual requirements. In addition to carefully regulated diet and mode of life, Dr. Weber has prescribed salicylate and bicarbonate of soda (gr. xv each) before meals, or Carlsbad water instead. Where the alkaline treatment did no good, or did not agree with the patient, he has ordered opium in small doses with benefit. In every case he saw good service from the use of massage judiciously applied, and the frequent use of baths. It is by the latter two remedies that the heart is kept fairly strong and active in this disease, which is as yet not curable, but manageable.

DR. GLENTWORTH R. BUTLER, Brooklyn; The generalization made in Dr. Weber's paper that the disease known as diabetes is merely a symptom of some underlying condition, is very valuable. Regarding the disease we call diabetes as a symptom, leads us to search for the under-

lying cause, and tends toward a more rational treatment.

In regard to diet, I can corroborate Dr. Weber's opinion that the very strict so-called diabetic diet is not always of service. In my own work, in a number of cases, the strict nitrogenous diet was not well borne, even though it caused the disappearance, partial or complete, of sugar in the urine. The general condition is impaired on the strict diabetic diet. The patient should have a fair variety of food, watching the general condition, and not giving up altogether the carbo-hydrates and the saccharine substances.

DR. ROBERT H. BABCOCK, of Chicago, presented

A REPORT OF CASES OF CHRONIC HEART DISEASES TREATED BY THE SCHOTT METHOD OF BATHS AND GYMNASTICS.

The purpose of this report was to call attention to the value of baths and light exercises in cardiac therapeutics, by which it is believed patients suffering with organic heart disease of chronic nature may be more promptly and lastingly improved than by drugs. A statement of the raionale and application of this system was given. With regard to the baths, Dr. Babcock said: "The improvement in the rate and quality of the pulse is an index of the degree of benefit derived by the patient. If not counteracted by exercise, this effect on the pulse will persist for an hour or two subsequently. Changes for the better in the size of the area of cardiac dullness and in the sounds may be noted likewise. This was demonstrated repeatedly last year both on myself by a competent Russian physician, and by myself on others. Careful percussion immediately before and after a bath of eighteen to twenty minutes' duration, showed a demonstrable retraction of the deep limits of cordiac dulness and the heart sounds were improved in strength, the second pulmonary being less accentuated, the second aortic stronger—in short, the abnormal difference between the two sounds before, being appreciably less marked after, the bath. Murmurs that are almost inaudible before become intensified; and conversely, some loud bruits are lessened in intensity. In short, so far as can be determined by physical examination, these baths appear to lessen the rapidity and increase the force of the heart's contractions, thereby occasioning a better filling of the great arterial system with corresponding depletion of the engorged veins."

The exercises supplement and reinforce the treatment by baths.

In a detailed report of 19 cases, 13 showed more or less improvement.

Contra-indications: "There can be no doubt of the danger of this form of treatment in degenerative changes of the blood-vessels and myocardium, such as aneurism and advanced arteriosolerosis, acute softening and great fatty degeneration of the heart."

DR. CHARLES E. QUIMBY, New York, referring to the subject discussed by Dr. Weber and Dr. Babcock, said: I have long felt that there is a fundamental defect in present methods of treating organic cardiac disease. We are constantly using the whip to stir up an overworked muscle. Digitalis, and the most of the so-called cardiac tonics are pure stimulants, furnishing in themselves no additional force. In the use of the nitrites, we do attempt something from the other side in the way of diminishing in the vascular resistance. Yet in so doing, we interfere directly with general nutrition, for the arterial contraction which follows every retardation of circulation from organic disease is only the physiological reflex that is intended to be compensatory and to restore the normal vascular flow. It is universally recognized that rest is the one absolute essential for the restoration of an exhausted or failing muscle. In the case of the heart, this can be at the best only relative, and however slight must entail a proportionate loss in the circulation. The ideal cardiac tonic is therefore mechanical: a force which can be substituted for that of the heart muscle, and made to maintain the circulation with a diminished expenditure of cardiac force. Some unusual results in the treatment of cardiac disease by means of mechanical measures lead me to believe this ideal is in a degree attainable. I can do no more than refer to it at present, as I hope at no distant date to embody my conclusions in full in a paper on the subject.

A NEW AND DISTINGUISHING SIGN OF LATENT ANEURISM OF THE AORTA

was the subject of a paper by DR. W. C.

GLASGOW, St. Louis. The sign referred to is the presence of a systolic sound, or thud, in the brachial artery, synchronous with the systole of the heart. This sound is sometimes accompanied by an arterial murmur. When this sound can be heard, aortic regurgitation can be excluded. Dr. Glasgow claimed that a positive diagnosis of aneurism can be made, even in the absence of all other signs or symptoms. Dr. Glasgow reported five cases of aneurism in which this arm sign could be heard. He also exhibited a patient from one of the Washington Hospitals who showed this sign.

DR. CHARLES E. QUIMBY, of New York, read a paper on

OZONE IN PHTHISIS, WITH ESPECIAL REFERENCE TO THE PNEUMATIC CABINET.

THE COMPARATIVE RARITY OF PHTHISIS IN THE HIGHLANDS OF PENNSYLVANIA AND THE ADJACENT COUNTIES OF NEW YORK.

by DR. GUY HINSDALE, Philadelphia, called attention to the low mortality from consumption in a district falling partly within New York and partly within Pennsylvania, embracing an area of 12,000 square miles. Throughout this region, there is, according to the best available information, a population of over 1,000 persons living to each annual death from phthisis. The Highlands of Pennsylvania particularly referred to, embrace the counties of McKean, Potter, Forest, Clarion, Elk, Cameron, Union and Sullivan. This entire region has an elevation of from 1,200 to somewhat over 2,000 feet; it is characterized by extensive forests, a dryer air, and lower temperature than prevails at the seaboard or lake shore.

As a member of a committee of the Association appointed to collect meteorological data of the resorts of this country DR. SAMUEL A. FISK, of Denver, read a paper giving

SOME METEORLOGICAL DATA OF COLORADO.

He claimed for Denver (or the region for which it stands) the advantages of elevation, atmospheric dryness, a small annual precipitation, a cool climate, a prevailing mild wind of only moderate velocity, and an open sky.

HON. MARK W. HARRINGTON, chief of the Weather Bureau, read a paper on

SENSIBLE TEMPERATURES

which aroused much interest. In his introduction, Prof. Harrington said: "The subject is so new that I am obliged to invent some terms to describe it." By "sensible" temperature, he explained, is meant that which is felt at the surface of the skin, especially where the skin is exposed as on the face and hands. To change a definite quantity of water from the liquid to the vapor state requires the utilization of a definite quantity of that form of energy which we call heat. On evaporation, this heat changes to other forms of energy; it is no longer sensible, and a sense of coolness results from its change. Thus is caused a reduction of temperature at the spot where the evaporation takes place; and while the evaporation continues, the surface from which it takes place is cooler than the general air temperature.

The reduction of temperature caused by evaporation depends on the rapidity with which evaporation takes place, and this, in turn, on the amount of moisture already in the air. In general when the air is saturated with moisture (that is, when the shade-temperature and dew-point are the same,) there is no evaporation, and the reduction is zero. When the air is supersaturated, condensation, the reverse of evaporation, takes place, heat is released, and instead of a reduction we have an addition to the temperature. But when the air is not saturated, a reduction of temperature takes place.

The amount of this reduction will be greatest where the air is driest, least, where the air is moist. In Washington, Philadelphia or San Francisco, the moisture is abundant, evaporation is relatively small, and hot weather feels hot. On the other hand, at Denver, Santa Fe or Prescott, the moisture is generally scanty, especially in hot weather, and the reduction is great. The most extreme case easily accessible is that of Furnace Creek, Death Valley, Cal.

It appears that in arid regions, the reduction may make hot weather not only

endurable but even agreeable and refreshing.

So far it has been only a question of temperatures in the shade. Temperatures in the sun are always higher, and may be very much higher. On a hot summer afternoon, a temperature of 130° in the direct sun's rays is not rare in any latitude of the United States. Sometimes this temperature reaches 140°, and occasionally it is even higher. The conditions for sensible temperatures already stated do not apply in such cases in part, it may be because of the failure of sufficient perspiration to give free evaporation; in part, because of the special effects which strong and direct insolation has on organic structures.

To obtain the beneficial effects of the reduction of temperature by evaporation, the shade must be sought, and the direct sun's rays avoided. The effects may be heightened by a natural or artificial breeze or wind; and for the parts of the body covered by clothing they may be obtained by adapting the clothing to the free passage of air and moisture.

Dr. Judson Daland, Philadelphia, gave a detailed report of three cases of

BERI-BERI,

with examination of the blood. The greatest interest in these cases surrounds the question of etiology. Beri-Beri has been observed in Japan, portions of Africa, and in the East and West Indies, and, as has been shown by Scheube and Baelz, it is an endemic peripheral multiple neuritis. Muira believed it to be due to fish, especially decomposed fish, while others attribute it to rice. These cases tend to bear out Muira's theory. The food of these men was almost exclusively fish and rice; some of the fish was dried; much was spoiled; the quantity was insufficient. The main facts, as given by Dr. Daland, seem to point conclusively to poisoning by some substance in rice or decomposing fish, probably of the nature of muscarin.

These three cases recovered, as did eight others, in the Brazilian Navy, reported by Dr. Gihon.

The whole tendency of opinion during the entire sessions seemed to be towards physiological treatment, the use of therapeutic means which are in the line of natural processes rather than the use of drugs, substances which are foreign to the organism.

How to Give a Fomentation.

Only those who have not tried the remedial effects of water, both hot and cold, doubt its efficacy in many forms of disease. It is perfectly safe to apply a fomentation in cases of severe pain befor a physician is summoned, and very often it relieves the sufferer before he arrives. This is the way to do it: Take half a dozen thicknesses of flannel large enough to more than cover the seat of the pain, fasten them together, for convenience in handling, wring them out of very hot water (use a clothes wringer to save the hands) and apply as hot as the patient can bear it. A dry flannel may be put between the skin and the wet cloth, if preferred, and over all a large flannel should be placed to keep the heat in. When the cloth begins to feel cold, it should be wrung again. Three or four applications will generally relieve a stiff neck or an attack of rheumatism in a joint.

A fomentation may be needed when there is no hot water in the house. It may be quickly prepared by wringing out the flannel compress in cold water, laying it between the folds of newspaper and putting it on a hot stove or holding it around a stove pipe until hot. The paper protects the cloth, and when steam begins to come out can be easily removed.

Tonic Mixture.

Absolute Alcohol in Erysipelas.

Dr. A. J. Oschsner (*Revue Internationale de Bibliographie Medicale*, No. 12, 1894,) has employed local applications of absolute alcohol in the treatment of erysipelas with the best of results. In twenty-four hours the temperature falls to the normal and the redness decreases considerably. This favorable action is said to be due to dehydration of the tissues and coagulation of the albumen by the alcohol. Mixed with water the alcohol will not act thus.

CURRENT LITERATURE REVIEWED.

IN CHARGE OF ELLISTON J. MORRIS, M. D., AND SAMUEL M. WILSON, M. D.

BRITISH JOURNAL OF DERMATOLOGY

or July contains an address on

the Typhoid Treatment of Skin Diseases

by Dr. Byrom Bramwell.

Owing to the great improvement noted in the skin of cases of sporadic cretinism and in myxœdema treated by typhoid extract, the author began using this agent in various kinds of skin diseases.

In psoriasis the author has had good results and feels justified in increasing the dose until a decided effect is noticed; but as some persons show great susceptibility to the drug, the commencing dose must be a small one. In other skin diseases it has not been possible to give a very extended trial to the remedy—it was used in only one case of chthyosis; but in that instance gave strikingly good results; in chronic eczema prompt improvement in one case, none in another; in acute eczema the effect seemed bad; in one case of pemphigus there was improvement, but the author inclines to credit hygiene and local measures more than the thyroid extract, so also in a case of exfoliatine dermatitis, although it seems theoretically to be suited to remedies of this class.

The author seems to think the thyroid acts through the nervous system, although he acknowledges that his reasons are theoretical only, and thinks it probable that the symptoms of Morvan's disease, sclerodactylia, anæsthetic leprosy, and syringomyelia would be relieved by its use.

For various reasons the tabloids of extract are preferred to the gland raw, or partly cooked, and the dose given varies both with the individual, and the disease he suffers from. In lupus and similar disorders, where the drug will be used for a long period the dose must be small; in psoriasis and ichthyosis where a rapid effect is desired and a large dose (running sometimes as high as thirty or forty or more fine grain tabloids daily,) is necessary. Extreme susceptibility to this drug is rare in cases of skin disease, but common in myxœdema, etc., and causes the following symptoms: headache, deranged stomach, diarrhœa, vomiting, acceleration of the pulse, rise of temperature, sometimes the symptoms of exopthalmic goitre (palpitation of the heart, and discomfort in the cardiac region, dyspnœa, etc. Suppurative lesions of the skin, though rare, may result, and in cases of diabetes the polyuria is apt to increase.

This paper was accompanied by a history of numerous cases, and photographs and drawings.

IN THE JOURNAL OF NERVOUS AND MENTAL DISEASE

for July, an address before the fiftieth annual meeting of

The American Medico-Psychological Association

by Dr. S. Weir Mitchell.

This paper criticises the methods still in use in asylums for the insane. In may cases the inmates are confined in groups, or separately, without work of any kind, with very little outdoor exercise, under nurses who have had no training to fit them for the position, One reason for this state of things is that superintendents of asylums live in the institutions apart from the rest of the profession and are not kept in touch with it by rivals, by young residents criticising them, etc.

The part politics is allowed to play in placing superintendents and residents in their places is greater in insane asylums than in general hospitals with the result of making the service less efficient, and the author proposes that this be remedied by competitive examinations.

In many asylums, again, the general medical treatment of a patient is utterly neglected—the modern means of diagnosis by blood examination, the microscope, ophthalmoscope, etc., are not in general use, and a case is mentioned where a question in regard to the electrical reactions in a special case was seemingly not understood.

The beneficial effect of steady outdoor employment on a number of patients in an asylum was instanced, and finally the views of a number of neurologists and other prominent and experienced physicians were quoted, and their views coincided with those expressed in the body of the paper; that the medical chief should command a salary large enough to attract a competent man; that he should have a large corps of competent assistants; that politics should play no part in the selection of these; that abundant work or interesting recreation be provided for patients; and that the business and medical supervision be in charge of two different men; and that training schools for nurses be established, and the nurses kept moving from ward to ward or from one institution to another until competent to command good wages outside.

EDINBURGH MEDICAL JOURNAL

for August contains

Three Cases Illustrative of Herman Freund's Law of Pedicle Torsion in Ovarian Tumors,

by Dr. A. R. Simpson.

The author cites three cases confirming the theory that there is a tendency for tumors situated in the right side of the body to rotate toward the left and for those in the left side to take the opposite direction. The first case was a dermoid of the right ovary with its pedicle twisted toward the left, and was in-

teresting from the family history that the mother and two aunts and a great aunt of the patient had suffered from dermoids of the face, or cancer of the uterus or mamma.

The second case complained mainly of the mechanical inconvenience caused by a large tumor which was found in removal to be attached to the left ovary, and twisted to the right.

The third case had a history of leucorrhœa, acting in back and limbs, longstanding dysmenorrhœa, etc. A parovarian cyst growing from the left side, twisted toward the right, and lying in the right side of the abdomen was found and removed. The uterus was three months pregnant and pregnancy terminated naturally at term.

Super-involution had been found in the second case, and the author thinks this a common accompaniment of tumors situated anywhere.

Dr. F. W. N. Haultain describes his experience in

The Electrical Treatment of Uterine Fibroids and Subinvolution.

The author applies his treatment only in cases where the uterus appears to be the organ mainly at fault, and distinctly enlarged. Cases where the ovaries are plainly diseased are treated by ovariectomy or some other procedure, and one or two cases are mentioned where the ovarian trouble was less obvious than the uterine, but where a failure of electricity led to a successful excision of the ovaries.

The author applies to the abdomen a piece of flannel twelve inches square soaked in salt-solution and in contact with a zinc plate connected with the battery—the intra-uterine electrode being platinum pointed and with a piece of rubber tubing to act as a sliding insulator.

When there is no bleeding, the negative pole is introduced into the uterus; as it is less painful than the other, but the positive pole is required if there is hemorrhage.

Most of the cases had already been curetted and cauterized without success, and although the author does not claim a cure in every instance, he says that the uterus was reduced in size in every one of his cases. Mental and physical vigor seem to be increased after a few applications have been made.

Probably the great benefit in this class of cases arises from the muscular contractions excited and from the decreased capillary circulation.

Dr. R. W. Irvine reports a case

Illustrating the Value of an Aseptic Blood Clot.

The patient was a boy who sustained a compound comminuted fracture of the tibia with rupture of the anterior tibial artery. Free hemorrhage ensued of course, but when the case was seen this had stopped and as the ends of the artery were not visible the larger bone fragments were cut in apposition, a few smaller ones removed, and a dressing of corrosive wool covered by a fenestrated splint of corrugated paper applied. Secondary hemorrhage occurred, but this having ceased when the case was seen again the dressing was reinforced without being removed.

On the third day, and at each subsequent dressing the clot was exposed, dusted with powder of iodoform one part, boracic acid seven. On the ninth day the last shred of the hardened clot was removed, leaving a small, clean, granulating surface. There was at no time any odor, and the results were so good that the patient plays foot ball, dances, etc., which result the author does not think would have followed if he had disturbed the wound to ligate the artery, and so have removed the protecting clot.

Dr. A. S. Miller describes

A Method of Excising the Wrist Joint

proposed to him by Dr. Henon Matson.

The knife enters toward the palman aspect one and one-half inches above the styloid process of the ulna and is carried down three inches reaching the metacarpal bone of the little finger, and passing along it for a short distance. At least an inch of the lower end of the ulna is now removed, then the carpus piece by piece leaving only the trapezium, then the heads of the metacarpal bones, and the end of the radius sawn off. Finally the trapezium is examined and, if sound, allowed to remain. A vessel at the radial side of the wound is best secured by turning the wound inside out.

The author packs the wound with iodoform gauze and begins passine motion in at most a week after the operation. The metacarpophalangeal joints are usually stiff before the operation, and should be freely flexed and extended as a preliminary to it.

The advantages claimed for this mode of operating are:

The single incision, and the slight deformity resulting, the efficiency of the drainage, and the ease of performance.

Other papers in this issue "The Commoner Varieties of Lupus Vulgaris and Their Treatment," by Dr. Norman Walker. "Pathological Report of Dr. Byrom Bramwell's Case of Cancer of the Breast, Spleen, etc.," by Dr. R. F. C. Leith. Lockhart Gillespie.

IN THE PHYSICIAN AND SURGEON

for July Dr. G. H. Sherman has a paper which he read before the Detroit Medical and Library Association on the

Eradication of Contagious Diseases.

The authur holds that so long as quarantine laws are enforced against such diseases as scarlet fever, and diphtheria, without compensating the families for loss of time, etc., there will be a general attempt to evade them, and their object will fail to a great extent.

The desire to evade these laws is particularly well seen when the disease breaks out in a dwelling connected with a bakery, ice

cream saloon or some similar resort, and of course these are the places where the worst results will follow.

The failure of the measures now in use seems due to the neglect of physicians to report the mild cases, the neglect of parents to call in physicians in cases they consider mild, fearing the quarantine, and the carelessness of neighbors who visit the sick saying they are not afraid of the disease.

The author proposes that the State Boards of Health take the matter up, and after satisfying themselves that no fraud is being practiced pay the quarantined families a stipulated sum weekly, while under restraint. In this way there would be an object to report a case at once and the restrictions could be carried out with the full cooperation of all concerned. The author thinks the money now expended for the same object would eradicate the disease if used in this way.

In his "Leipsic Letters" Dr. Collins H. Johnston describes the method used by Prof. Epstein in his Prague clinic for detecting worms in children,

He passes a catheter a short distance into the rectum and microscopically examines the fecal mass removed for the ova. The ova of round worms pass away so constantly that they are uniformly distributed in the feces and their absence proves the absence of the worm. Tapeworms he says deposit eggs also but less regularly than the other variety, so that it requires several examinations to declare the absence of these.

Other papers in this issue are: "An Address on Anthropology and Ethnology," by Dr. Edward C. Mann. "Urethral Stricture—Cause and Treatment," by Dr. Frederick W. Robbins, and the report of a case in which severe nervous symptoms were relieved by treating the eye, by Dr. John S. Owen.

PERISCOPE.

MEDICINE

Muscular Rheumatism.

According to Leube (*Deutsche Med. Woch.*) muscular rheumatism is not a local disease, but a general infective disorder with special localizations in the muscular system. The mode of onset of the disorder varies, but is sometimes marked by shivering and prodromal fever, and by malaise of some duration. In some cases muscular pains may be widespread, and occasionally endocarditis is observed. Taking a series of about 200 cases, he found that fever was present in about one-third; it was seldom higher than 102° F., and generally fell after two days in hospital either rapidly or after some irregular fluctuations. In one-sixth of the cases there was a cardiac murmur at the time of admission, it is generally supposed that endocarditis; which is so common a "complication" of joint rheumatism, scarcely ever occurs in relation with muscular rheumatism. It is not possible to say in how many of the cases in which a murmur was observed this was present before the onset of the muscular rheumatism, but it was noticed that in half the cases the murmur grew fainter or disappeared while the patient was under treatment, and that whereas in all the cases together fever was observed in one-third only, it was present in two-thirds of those in which there was a murmur. Moreover, in a few cases the murmur was observed to appear after the onset of the muscular rheumatism. Three such cases are related by Leube, but in one there was at a later stage muscular rheumatism and in another the patient, at the time the muscular rheumatism came on, was under treatment for gonorrhœal urethritis, vaginitis, and cervical endometritis. Leube states that he has seen joint rheumatism in several cases, and points out that muscular rheumatism is frequently observed after affection of the joints. Pleurisy was in a few rare cases observed as a complication of muscular rheumatism, but albuminuria only once. Leube concludes that it is highly probable that the infective material in muscular rheumatism is an attenuated form of the virus of acute rheumatic arthritis. In Wurzburg, where his observations were made, the cases of muscular rheumatism coming to the clinic were, as a rule, few in number and isolated, but at one time recently a large number of cases applied, so that half a ward was filled with them; this would appear to indicate an epidemic influence. He only mentions the question of treatment incidentally, but would seem to have relied on salicylate of sodium.—*Brit. Med. Jour.*

Treatment of Inoperable Carcinoma of the Uterus.

Dr. Bernhart (*Amer. Jour. Med. Sci.*) Dr. B. (*Centralblatt fur Gynakologie*, 1893, No 39) has obtained highly satisfactory results from parenchymatous injections of salicylic acid in alcohol (6 parts of the acid and 60 parts of the alcohol.) About 30 minims are injected into the neoplasm in eight or ten different places Some patients complained of severe pain during the injections, while others had none at all. There were slight elevations of temperature. The results observed were as follows: Within three days after ulcerating nodules had been thus treated the ulcerations had healed, and there was marked retraction at the sites of the punctures. After repeated

injections (at intervals of four days) the affected nodules had greatly shrunken and presented a smooth surface on which epithelium later developed. Meantime the patient's general health improved, pain and foul discharges ceased, and there was no further hæmorrhage. These results were obtained in six cases of inoperable carcinoma of the cervix, though the patients had not been kept under observation long enough to report as to their subsequent condition.—*Am. Med. Surg. Bulletin.*

Some Common Mistakes in the Treatment of Syphilis.

Dr. George H. Fox read a paper on this subject. Many physicians, Dr. Fox said, hold to the belief that syphilis is an incurable disease. On the contrary, the disease in every case tends to run a natural course and get well of itself. If a person suffering from syphilis inherits a sound constitution and takes care of himself, the prognosis is extremely favorable even though no treatment whatever is adopted. With the methods of treatment at our command, no disease furnishes such good results.

Another common mistake arises from the belief that mercury and potassium iodide are practically the only remedies we have at our command in the treatment of syphilis. While they are both very potent remedies, yet complete reliance on them often causes serious injury to the patient. In anemic patients iron should be regarded as an antisyphilitic remedy. In strumous individuals, cod liver oil is very serviceable. The alleviation of mental anxiety and the adoption of hygienic rules are of the utmost importance in certain cases. The mistake is too frequently made that we treat the disease instead of the patient.

Another fallacy is the belief that a certain definite period of time is required to effect a cure. Some say two years, others three, etc. The course of syphilis varies in different individuals, and the period of treatment must likewise vary, according to the severity of the case. One case of syphilis may require twice as much medicine as another, and the period over which treatment should be extended may be twice as long.

Another common error is that many ills occurring in a syphilitic subject are treated as though they were of syphilitic origin. The fact that a patient has syphilis does not exempt him from non-specific disorders, yet the physician is very apt to jump to the conclusion that such disorders are the result of the syphilis, and to treat them accordingly. In many cases lesions on the tongue and oral mucous membrane in syphilitics remain unaffected by specific treatment, and the fact should be borne in mind that similar lesions may occur in persons who have not had syphilis, as the result of digestive disturbance. Even if they are syphilitic, such lesions may persist in spite of specific remedies unless the digestive errors are corrected.—*Journal of Cutaneous and Genito Urinary Diseases, Atlanta Med. and Surg. Journal.*

Chronic Cocainism.

J. B. Mattison, (*Union Medicale du Canada*), the author published a very careful study of the effects of the use of coca or cocaine on the different parts of the organism, as the lungs, the heart, the liver, the kidneys and the nervous system. These investigations prove that some of the properties claimed for erythroxylon coca, as its stimulating action on the nervous and reproductive systems are false, as the coca and cocaine rapidly diminish the sexual appetite. Under the influence of the drug, the temperament is modified, the patient becomes idle, unclean, selfish and neglectful of his social duties, in short, the disturbances produced resemble those of the last stage of morphinism. In South America, many of the people who use coca are phthisical.

In recent cases, the drug may be suppressed suddenly, the pain and insomnia being combated by phenacetine, chloralmid, sulfonal, paraldehyde, and bromhydrate of hyoscine. In cases of long standing, it is better to proceed gradually and replace cocaine by injections of benzoate of caffeine.—*N. Y. Therapeutic Review.*

Migraine.

The Relation Between Urticaria in Infants, and Rickets and Dilatation of the Stomach.

Drs. Funk and Grundzach (*Monatshft. f. prkt. Dermat.,*) say our authors are firm believers in a close relationship between urticaria and rickets. In the summer of 1893 they met with forty-five cases of urticuria in children under two years of age, and all of them were rachitic. In all of them there were also digestive disturbances, and this was coupled with evident dilatation of the stomach. They all suffered from colic, constipation, and thirst. In almost all cases they were fed too frequently. The treatment best adapted to these cases was regulation of the feeding and hygiene of the child. In acute outbreaks they administered at night a teaspoonful of a mixture of antipyrin 1.50 gme. (gr. xxii), water and syrup each 25 gme (ʒ vi m xv). Externally they used diluted vinegar followed by powdering. In cool weather lukewarm salt baths were helpful. In summer baths were omitted.—*A. M. S. Bull.*

Nitro-Glycerin in Vomiting.

Dr. R. Humphreys (*Brit. Med. Jour.*) has used nitro-glycerin systematically for the last three years in every form of vomiting he has met with, and as it is a drug which is not incompatible with other drugs likely to be employed under such circumstances, while it has proved of the greatest service, he thinks that it may be as well to record this use of it, as he can find no mention of it as a general remedy in vomiting. In vomiting in gastric catarrh, whether adult or infantile, acute or chronic, alcoholic or anemic, he has found it to act almost as a specific. The vomiting ceases at once. In a case of vomiting of advanced pregnancy, he found it to be of the greatest service, and in some cerebral cases it also markedly checked the sickness. In peritonitis alone it increased the vomiting, not, however, to a distressing extent, and the effect soon passed off. He ventures to suggests that this may prove a point of diagnostic value in doubtful cases. In vomiting in connection with pulmonary phthisis it proved of little value, where atropine stopped it for the time. In combination with catechu, it acted very well in several cases of lienteric diarrhœa. The vomiting of influenza was often relieved by it, though not to the same extent as by atropine. He has seen no bad effects from its use.—*N. Y. Med. Times*, June, 1894.

The Treatment of Eclampsia.

Krong (*Centralblatt fur Gynakologie*) in discussing the treatment of eclampsia at the Eleventh International Medical Congress at Rome, stated that as long as so little of the etiology and pathological condition of eclampsia is known, a rational therapeusis cannot be formulated, at present it is limited to the combating of the convulsions. The average mortality by this treatment is from 20 to 30 per cent. He believes that while the convulsions are controlled by narcotics, the eclampsia as such continues to exist. The course of the condition can be unfavorably influenced by large doses of narcotics. In the Leipziger klinik the treatment by morphia has been given up for one and a quarter years. Its place has been taken by forcible delivery in the eclampsia of pregnancy or of labor. In Leipzig to the present time there have been eighteen cases with one death,—*i. e.* 5.5 per cent. mortality. By the use of this method there are two points especially to be observed.

(1) The controlling of the hemorrhage.

(2) The observance of asepsis.

In two-thirds of the cases there was more or less violent hemorrhage from cervical tears.

The hemorrhage was controlled in all the cases by tamponnade of the utero-vaginal canal with aseptic gauze. The 20 per cent. iodoform gauze advocated by Duhrssen should not be used on account of the accompanying kidney complication. For the same reason intrauterine irrigation with antiseptics should not be employed from the diminished excretion by the kidneys of any that might be absorbed. Asepsis must be especially and rigidly observed in this operation. Despite the greatest care, over one-half of the operated cases are infected; the infection limiting itself in the most of the cases to the endometrium. Recovery follows in most of the cases rapidly.

The treatment of eclampsia in the Leipziger klinik is the following:

Narcotism only during the operation.

Forcible delivery.

In threatening edema of the lungs, venesection, abstracting 600 to 800 grammes of blood.—*Univ. Med. Magazine.*

Pyoktanin Internally in Malignant Growths of Internal Organs.

Poisoning by Illuminating Gas.

The various jokes on the countryman who blows out the gas shows to what an extent this accident occurs and that it is not often done intentionally is the opinion of Dr. John W. Shaw, of Washington, D. C., (*Virginia Medical Monthly*), who believes that 94 or 95 per cent. of cases are due to either carelessness, ignorance or accident.

His theory is that the gas poisons in three different ways. First. By the gas replacing, to a greater or less extent, the atmospheric air, consequently reducing the supply of oxygen. Second. By the direct poisonous properties of the heavy and light carburetted-hydrogen, when mixed with air and absorbed through the lungs. Third. By the collection of carbon dioxide in the body for the want of sufficient interchange of gases neces-

sary to remove it. He thinks that it is the retention of effete material in the system that does the harm and it is as much the carbonic acid gas as the illuminating gas which cripples the blood corpuscles which are not able to carry off the carbonic acid gas, thus overwhelming the respiratory centres and causing death.

He does not believe in the use of oxygen but thinks that transfusion of blood would be the most rational form of treatment in extreme cases, for it immediately supplies the system with the hemoglobin, of which it is in such great need. This, combined with fresh air, artificial respiration, heat, and stimulants, are sufficient to keep one busy until life or death removes the responsibility.

As a stimulant he prefers hypodermic injections of nitro-glycerine as recommended by Kloman, to ammonia by the rectum.

A New Mercurial Salt for Injection.

This is the double hyposulphite of mercury and potassium. It presents itsef in the form of colorless crystals, easily soluble in water and producing no precipitate in solutions of albumen. The proportion of mercury which it contains is 31.4 to 100.

This salt has, according to Dr. Dreser, the remarkable property of being decomposed by electrolysis in such a manner that its mercury goes to the anode, for in the preparation the molecule of mercury does not exist in the metallic state, but in the form of a mercuric acid.

Injections of this compound are, according to Dreser and Camerer, no more painful than ordinary injections of morphine. They produce no irritation or local caustic effect, and the dose may be exactly regulated, 1 gramme (15 grains) of chloride of mercury corresponding to 2.32 grammes (nearly 36 grains) of the hyposulphite of mercury and potassium. The solution for injection is made in the proportion of 0.25 gramme (nearly 4 grains) in 10 grammes (2½ drachms) of distilled water. From ½ to 1 cubic centimetre of the solution is injected, corresponding to about $\frac{1}{12}$ to $\frac{1}{6}$ grain of corrosive sublimate.—*Med. Bulletin.*

Treatment of Typhoid Fever.

Dr. Osler, of Baltimore, in discussing the treatment of typoid fever at a recent meeting of the Clinical Society of Maryland, said that the antipyretic drugs were entirely superfluous in this disease. The cold bath is more efficacious, but is not always available in private practice; but all the good effects of the bath can be obtained by sponging. A good nurse or doctor can sponge the patient so effectually that the fever will be satisfactorily reduced. When temperature is high, ice sponging—not with ice water, but with lumps of ice—over the back and legs will reduce the temperature very pleasantly to the patient, and satisfactorily to the doctor. Delirium and stupor are also effectively treated by ice sponging. The use of modern antipyretics in typhoid fever is, in nine cases out of ten, positively hurtful. They reduce the heart's action, and cause weakening sweats, and their use is an unmitigated evil. In the great majority of cases the treatment may be taken from old Dr Nathan Smith, of Yale, which was pretty much that of to-day—plenty of fresh air, liquid diet, and cold externally. He was in the habit of turning out the friends of the patient, putting the patient on the floor, and then dashing water, handed through the window by an assistant, over the patient—*Canadian Practitioner.*

Cancer of Throat.

Dr. James M. French says, in the Ohio Medical Journal, that he has recently used with gratifying results, the following formula:

℞

Pyoktanin	.....	3j.
Chloroformi	.....	q. s. ut. solv.
Benzoinol	.....	3iv.

M. Sig.: Spray at intervals of one or two hours.

Neuralgia.

For stubborn neuralgia try the following:—

℞

Antipyrin	.....	3iss.
Caffeine	.....	3ss.
Ext. cannabis Ind	.....	
Ext. aconite	.....āā	gr. iiss.
Hyoscyami hydrobromat	.....	gr. ½.

M. et ft. caps. no. xxx.
Sig.: One every two or three hours.

—*Prescription.*

Addisonian Intoxication.

Dr. Chauffard has recently contributed an interesting paper to *La Semaine Medicale*, devoted to the consideration of the pathological condition which exists in Addison's disease. The writer notes the experiments of Abelous and Langlois in support of the view that the peculiar phenomena which occur in Addison's disease are due to the accumulation within the body of certain poisons which it is the duty of the supra-renal capsules to destroy. This is made clear by the following facts developed by the experiments referred to:

A frog deprived of its supra-renal capsule dies in forty-eight hours in the summer time, and in from twelve to thirteen days when in a state of hibernation, the length of the survival after the operation being directly proportioned to the activity of the animal.

When one capsule, or even a considerable fragment of a capsule, is left in place, the animal survives.

If after the destruction of both capsules a fragment of the kidney of another frog with the corresponding capsules attached in its normal condition, is inserted in the dorsal lymphatic sac, the life of the animal is prolonged to five or six days in the summer time.

The blood of a frog paralyzed and dying as the result of the removal of the capsules, is toxic to a frog recently operated upon, producing rapid paralysis and death.—*Modern Medicine.*

Codliver Oil.

Before the Therapeutical Society M. Patein read a very complete and interesting report on codliver-oil. It is the most digestible fatty food, probably on account of the biliary principles which it contains. Moreover, it possesses important stimulating and thermogenic properties, due to the phosphorus and iodine which it includes in organic combination, and also to the numerous alkaloids isolated by MM. Gautier and Mourgues. These alkaloids — butylamine, amylamine, oxylamine, dihydrobutyline, aselline, morrhuine, with morrhuic acid, etc.—exist principally in the light-colored oil, and result from an auto-digestion of the livers at the end of three or four days of maceration. It is an auto-digestion, and not a putrefaction, for at that period the livers have an acid reaction, whereas during putrefaction the reaction is alkaline. M. Patein touched rapidly upon the applications of codliver-oil: rachitis, pulmonary tuberculosis, rheumatism,—in which its action appears doubtful,—its external application in dermatoses, etc. He pointed out its incoveniences, its repugnant taste, purgative effect in large doses, accumulation of fat in the liver if its use is abused. He advises that the dose of 3 ounces should never be exceeded, that it should never be administered except in winter, that its exhibition should from time to time be suspended. M. Patein also recommends that the sides of the glass from which it is taken should be moistened in order to prevent the oil from adhering to the vessel. The patient should swallow it at one draught, and, after taking it, should wash the mouth with some aromatic water.—*Med. Bulletin.*

The Various Forms of Blood Cells.

The classification of the corpuscles of normal human blood has been much expanded by Ehrlich, whose groupings are followed by Dr. W. S. Thayer in the *Johns Hopkins Hospital Reports*. The red corpuscles, the blood plates, and the colorless cells make three easily demonstrated kinds of corpuscles in human blood, but the colorless cells need to be subdivided into five varieties, according to their differing reactions to staining fluids. Lymphocytes are the small colorless cells approaching the red corpuscles in size, the body of the lymphocytes being filled with a large, round, deeply staining nucleus, while the protoplasm is represented by a small ring about the nucleus. Uninuclear leucocytes are larger cells, which have a relatively large amount of protoplasm. Transitional forms are those cells which have a similar appearance to the two foregoing varieties, but differ from them only by the nucleus showing certain indentations which may give to it the appearance of an hour-glass. Multinuclear neutrophiles are cells perhaps a trifle smaller than the large uninuclear elements, and having a single nucleus so irregular in shape that it may appear as several nuclei under a single focus of the microscope, thus forming a characteristic polymorphic nucleus, with a thick non staining granulation. Eosinophiles usually have a polymorphous nucleus and contain the larger and more refractive eosin-staining granules. The protoplasm of the lymphocytes usually takes a red violet color with a triple staining, while that of the large uninuclear elements has but a slight affinity for coloring matters. There exist, however, in all human blood a number of uninuclear and some multinuclear elements, which have a protoplasm that remains entirely unstained, looking like a white spot or a small vacuole in the middle of the stained cell. Nucleated red blood cells, or normablasts, are found in the bone marrow. In pathological conditions there are many abnormal varieties of blood cells.

Arsenic in Recurrent Herpes.

Hutchinson is of the opinion that in this drug we have a means of controlling successive attacks of herpes. He gives a record of a case of "herpetiform pemphigus" in which formation of blebs was completely arrested by exhibition of arsenic. The disease returned when treatment was intermitted, but a continuance for two years produced a practical cure.—Dr. Johnston, in *Journal of Cutaneous and Genito-Urinary Diseases.*

Whooping Cough.

Fluid extract eucalyptus is a valuable remedy in whooping cough. When combined with extract glycyrrhiza it is not unpleasant to take.—*Kansas Medical Monthly.*

Hypnology.

At a meeting of the *French Hypnological Society*, several interesting cases were related, from among which we report the following:

Dr. Voisin states that C——, a young woman æt 19, has been at the Salpetriere since the age of seven, having been admitted as an epileptic. Every three months, and several times in succession, she was taken with very severe torticollis. During the night, the patient dreams, complains of her neck, and awakes with torticollis. See was considered by Dr. Voisin as being hysterical, and under the influence of hypnotic suggestion she was cured.

Dr. Regnault reported the case of a woman suffering from amenorrhœa and hysterical monoplegia, affecting the left leg. These conditions had persisted for a year when she was submitted to treatment by suggestion. The idea was suggested that massage would cure the anæsthetic trouble, but no mention was made to her of the amenorrhœa. Notwithstanding this, she was taken with rather severe flooding after the first seance, and after three applications of massage she was completely cured.

Dr. Ernould spoke of the value of suggestion in the different diagnosis of organic nervous lesions from the hysterical conditions which sometimes simulate them. He reported some cases in which this mode of diagnosis has proved of value.—*N. Y. Therap. Review.*

The Moment for Blood-Letting.

Sir Benjamin Ward Richardson considers blood-letting sound practice under several conditions of disease, notably the following: In acute spasmodic seizures, as in spasm of croup, in colic, and in angina with symptoms of oppression from distension of the right side of the heart with blood; in acute pain, membranous or spasmodic, as in sudden pleuritic or peritoneal pain, or in pain from passage of a renal or hepatic calculus; in acute congestion of vascular organs, as of the lungs or brain, apoplectics; in cases of sudden shock or strain, as after a fall or blow, sun-stroke, or lightning-shock; in exceptional cases of acute hæmorrhage unattended by pyrexia.

The blood may be drawn from a patient without fear of direct danger from the practice when the veins are full and the pulse firm, regular, full and tense; the pupil natural or contracted; the body at normal heat, or, with brain symptoms, raised in temperature; the bronchi free of fluid, and the sounds of the heart well pronounced.—*Asclepiad.*

Sciatica.

Dr. Metcalf orders:

℞ Tinct. aconit.....
Tinct. colch. sem.....
Tinct. bellad.....
Tinct. actæa racem .....āā equal parts.

M. Sig.: Six drops every six hours.

—Medical and Surgical Reporter.

Periodical Neuralgia.

Dr. William H. Thomson, of New York, has had good results in severe, long-standing, and rebellious cases from the use of ergot.

The fluid extract of the drug was employed, combined with an equal quantity of elixir of cinchona, to obviate its tendency to cause nausea. Two drachms of this mixture were to be taken in water as soon as the premonitory symptoms of headache were noticed, and the patient was advised to lie down and keep very quiet. If after an hour the headache continued, a second similar dose was taken, and then a third in another hour, if necessary. As nausea was such a general accompaniment of this affection, it was provided that if either of the doses be vomited it should then be taken in an enema of two ounces of water.—*American Practitioner and News.*

Antipyrine as a Sedative in Prostatic Hypertrophy.

Dr. J. Brik (*Med. Week.*) says the author considers antipyrine an excellent means of calming certain urinary disturbances observed in cases of hypertrophy of the prostate. Under the influence of this substance, it is claimed that the frequency of micturition during the night is notably diminished, while at the same time urine is passed more easily and with less pain. The antiyprine is administered to prostatic patients, especially during the acute exacerbation of the symptoms, in doses of 50 centigrammes to 2 grammes (7½ to 30 grn.) in 60 grammes (2 fl. oz.) of tepid water, in the form of enemata. In certain cases, Dr Brik advantageously injected into the bladder, after first thoroughly irrigating this organ, 20 to 30 grammes (5½-8 fl. dr.) of a 2 per cent. solution of antipyrine. In other cases he instilled into the prostatic portion of the urethra 10 to 12 drops of a 5-20 per cent solution of antipyrine, using for this purpose Güyon's syringe. These instillations at first determined a smarting sensation of short duration, soon replaced by analgesia which persisted for some time.—*A. M. S. Bull.*

Erysipelas.

During a long practice I have found the following local application most excellent:

℞ Aquæ puræ..... Oj.
Ferri sulphatis. q. s. facere solutionem ad saturandum.....

Sig.: Keep a cloth wet with the mixture to the parts affected.

℞ Iodoformi..... 5j
Olei rosæ..... gtt v.
Collodion..... 5x

M. Sig: Use as a local application four or five times daily.

The burning pain is relieved at once.

℞ Acidi carbolici (liquid).....
Spir. vini rectificati.....
Tincturæ iodini.....āā 5j
Olei terebinthinæ..... 5ij
Glycerini..... 5v

M. Sig.: Paint parts affected three or four times daily.

℞ Salol..... 9ij
Iodol..... 9j
Glycerini .....
Collodion.....āā 5j

M. Sig.: Apply to affected surface three or four times daily.

—Dr. N. B. Kennedy, in the *Texas Sanitarium.*

The Strychnine Treatment of Pulmonary Consumption.

Next to rest and food, strychnine in large doses, is the most important agent in the treatment of pulmonary consumption. Begin with $\frac{1}{32}$ of a grain, and gradually increase to $\frac{1}{16}$, $\frac{1}{12}$, or $\frac{1}{8}$ of a grain, or even larger doses, given four times a day According to the author it does not produce albuminuria or diabetes, as is generally supposed. It alleviates the loss of appetite, the vomiting, the constipation, the nervousness, and sleeplessness, the pain in the chest, the cough and expectoration, the dyspnœa, the weakness of the heart, and acts as a blood-builder in an eminent degree Its usefulness rests, of course, on its influence over the nervous system, and is another link in the chain of evidence which shows that in the great majority of cases pulmonary consumption is the direct result of primary disease of the pulmonary nerve supply.—Thomas J. Mays, M. D., in the *Coll. and Clin. Record.*

Concerning the Treatment of Abortion.

Eckstein (*Prager medicinische Wochenschrift*, Nos. 17 and 18, 1892) as assistant in Martin's clinic, has had opportunity to study sixty cases of abortion treated by Martin's principles in his private clinic in Berlin. He attaches the greatest importance in the curettage of the uterus to the thorough emptying of the tubal angles, as remains of placenta or portions of membranes are especially liable to be attached there. In nearly all the cases Eckstein followed a manual or instrumental emptying of the uterus with curettage, by the idea that an imperfect separation of the decidua and a consequent endometritis is thereby to be prevented. The results of this method were very satisfactory. From his experience he deducts the following:

1. The instrumental method of the treatment of abortion is the only rational one.
2. The recognition of the cause of bleeding from the uterus is of the greatest importance, and therefore in every uterine hæmorrhage a careful examination should be made.
3. Ergot and similar drugs should only be used when the uterus is empty.
4. If abortion is in progress, a tamponade of the vagina is only indicated when there is no dilatation of the os uteri.
5. When the dilatation of the os is sufficient, the emptying of the uterus, in spontaneous abortion, is indicated.
6. In large embryos, from the fifth month on, one conducts the abortion as in labor at term.
7. In abortion attended with fever and the decomposition of the product, the uterus should be emptied of its contents as quickly as possible.
8. A thorough curettage of the endometrium should follow every emptying of the uterus in abortion.—*Western Med. Reporter.*

Proper Time to Give Acids, Alkalies, Etc.

Alkalies should be given before food. Iodine and iodides should be given on an empty stomach, when they rapidly diffuse into the blood. If given during digestion the acids and starch alter and weaken the action. Acids, as a rule, should be given between the digestive acts, because the mucous membrane of the stomach is in a favorable condition for the diffusion of the acid into the blood. Acids may be given before food when prescribed to check the excessive formation of the acids of the gastric juice. By giving it before meals, you check the osmosis stomach-ward of the acid-forming materials. Irritating and dangerous drugs should be given directly after food, such as the salts of arsenic, copper, zinc and iron, except where local conditions require their administration in small doses before food. Oxide and nitrate of silver should be given after process of digestion has ended; if given during food, chemical reactions destroy or impair their special attributes, and defeat the object for which they were prescribed. Metallic salts, especially corrosive sublimate, also tannin and pure alcohol, impair the digestive power of the active principle of the gastric juice, so should appear in the stomach during its period of inactivity. Malt extracts, cod liver oil, phosphates, etc., should be given with or directly after food, so that they enter the blood with the products of digestion.—*Ex.*

SURGERY.

Causes of Sexual Debility.

Dr. F. R. Sturgis gives the following summary of his views at the termination of a very instructive paper:

1. That the cases of sexual debility which are marked by imperfect erections and by premature emissions, are usually, if not entirely, due to hyperæsthesia of some portion of the urethra.
2. That masturbation has very little, if anything, to do with it, beyond the fact that if indulged in to excess, it may induce a tendency toward this hyperæsthetic condition, but this is no more marked in masturbators than it is in those persons who indulge to excess in the venereal act.
3. That organic stricture has little, if anything to do with it; but that associated with this hyperæsthetic condition there is an irritable condition of the canal which produces spasmodic contractions of the urethra upon attempts to pass instruments, oftentimes during the first act of micturition and at the time of connection.
4. That varicocele plays no unimportant part in these cases.
5. That neuralgia of the testis, if a cause of this disease, induces it merely as a secondary consequence to the pain which is one of the distinguishing features of this disease.
6. That tuberculosis, syphilis and gonorrhœa may also play their part and should all be reckoned with in summing up the causes which may induce this peculiar and depressing condition of affairs.—*Gaillard's Med. Journ.*

Impermeable Stricture of the Urethra; Dilatation by Hydrostatic Pressure.

Marx (*Semaine Medicale*) says the following method of procedure has been recommended in cases of "impermeable" stricture of the urethra:

The urethra is distended, by means of a syringe, with a mixture of equal parts of a four per cent. solution of cocaine and of 1:1000 corrosive sublimate, and while the fluid is prevented from escaping, a catheter or bougie is introduced which passes through the stricture with great ease. This is ascribed to a funnel shaped dilatation of the stricture caused by the pressure of the fluid, but we are inclined to believe that the cocaine, by reducing the congestion of the urethral mucous membrane may be an important element in this treatment.—*N. Y. Therapeutic Review.*

GYNECOLOGY.

Senile Endometritis.

At the Annual Meeting of the Medical Society of New York, February 6-8, 1894, a paper upon this subject was presented by Dr, A. J. C. Skene, of Brooklyn, of which the *American Journal of Obstetrics* contains the following abstract:

There was a general opinion that endometritis ended in recovery at the menopause, but Dr. Skene had seen it continue after this period, and a good many cases in which it had arisen subsequently. He had concluded, eighteen years ago, that senile endometritis was a distinct affection which deserved more attention; it was quite different from the endometritis of earlier life.

In pathology senile endometritis might be limited to the cervix, but as a rule it involved the entire mucosa. It was usually suppurative, the discharge being sero purulent, and when it began as a catarrh it usually progressed to the suppurative form. The epithelium of the endometrium became almost entirely lost; granulations of low vitality sprang up; minute extravasations of blood were seen, with small pigment spots; atrophy of the muscular tissue was present, which caused inversion of the mucous membrane; laceration of the cervix was a frequent accompaniment; there was often partial or complete stricture of the os internum or externum; pus would be discharged and again accumulate. When the disease had existed long enough to destroy the mucous membrane, it might end in cicatrization, but it could hardly be called self limiting.

As to causation, continuation of endometritis acquired before the menopause accounted for some cases. Some of the severe ones, involving the body of the uterus, were caused by displacement, especially retroversion, which interfered with the escape of the secretions. Stricture of the os internum acted in the same way. In the majority of cases the occlusion was the result of inflammation. Acute or latent gonorrhœa might cause it, but he was not sure that he had ever seen acute gonorrhœal inflammation after the menopause. Inattention to cleanliness might cause it, also fibroma.

The first symptom to attract the attention was the discharge, and this varied according to the extent and stage of the inflammation. When there was interference with drainage there were more pain and constitutional disturbance. There might be slight chronic sepsis; digestion was interfered with; there was apt to be a dry, bronzed skin, suggestive of malignant disease. In case of true stenosis the pain was acute and compelled the patient to rest in bed. The discharge differed from that of leucorrhœa in being less tenacious; its color, indicated, too, that it was sero-purulent. The differentiation from specific disease and malignant disease called for the use of the microscope. In adenoma there was menorrhagia, which did not occur in senile endometritis.

BACTERIOLOGY.

Flies and Cholera.

Dr. J. G. Sawtchensko recently conducted a series of minute experiments, the result of which has been to demonstrate that the comma bacillus to which cholera is due, may be propagated and disseminated by means of flies, since the microbe when swallowed by a fly not only resists the action of the digestive fluids of the insect, but multiplies in its intestinal canal. This same fact has been observed as regards the vibrion of Metchnikoff, and in relation to both the ordinary small fly and the larger species. Grassi showed, long ago, that the eggs of certain parasites, particularly tapeworms and oxyuris, may pass through the intestinal canal of a fly, and may thus be brought in contact with the food. Dr. Joseph, of France, has observed the microbes which give rise to cholera nostras in the blue fly and in the golden fly (Lucilia Cæsar.)

The immense importance of these facts is apparent when we consider the fact that a single microbe, when falling in a suitable medium, may give rise to an infinite number. These facts are sufficient to explain the observation frequently made in outbreaks of cholera, that the disease makes its appearance at many independent foci, and not infrequently it is utterly impossible to trace any direct connection between the early cases. This was notably the case in the last outbreak in New York City.—*Modern Medicine.*

An Improvised Method of Securing the Trendelenburg Posture.

Dr. Geo. W. Cale, St. Louis, in *The Hot Springs Medical Journal* shows how this position may be secured for operation in the country or in the most modest home by placing an inverted chair upon an ordinary kitchen table, and after placing a pillow on the back of the chair covering the whole with a sheet.—*Southern California Practitioner.*

ARMY AND NAVY.

CHANGES IN THE U. S. ARMY FROM JULY 29, 1894, TO AUGUST 4, 1894.

Leave of absence for one month, to take effect about August 6, with permission to apply for an extension of one month, is granted First Lieutenant R. S. Woodson, Assistant Surgeon.

Leave of absence for one month, to take effect about October 1, 1894, with permission to apply for an extension of one month is granted First Lieutenant F. A. Winter, Assistant Surgeon.

First Lieutenant A. N. Stark, Assistant Surgeon, now at Fort Sam Houston, will proceed to Camp Eagle Pass, Texas, and report for temporary duty.

Leave of obsence for one month, and twenty days, to take effect on or about August 15, 1894, with permission to leave the United States, is granted Lieutenant Colonel Alfred A. Woodhull, Deputy Surgeon general.

ORIGINAL ARTICLES.

A PLEA FOR THERAPEUTICS.

WM. B. WARNER, M. D., Red Bank. N. J.

This is an age of investigation. An age which might almost be called ultra-scientific. An idea or a proposition which is born to-day, must come into existence prepared to fight for its survival. It will not be taken on faith. It will not be accepted as a truth because its progenitor calls it such; but it must come stripped of all debatable factors in order to meet the stony glare of to-day's scientific judgment.

It must expect to be weighed and measured. It must be put to the test of theodolite and chain, crucible and retort, microscope and spectroscope. In fact it must while still upon the threshold of science, stand with such form and color, that of it, it may be said "This is a condition and not a theory which confronts us." This principle of delving after truth, of separating the chaff from the wheat, is not confined to *new* ideas, but is also brought to bear upon theories and corolaries which are moss-grown and hoary with age. Among the rattling of dried bones, the probing of dogmas, the shaking of faiths, and the sifting and culling which is the tendency of the hour, how can therapeutics, which as a science is manifestly far from being exact, hope to escape?

And it goes without the saying that it has not escaped. In the general onslaught which has been made along the line of battle against tradition and theory, therapeutics has certainly borne its share of the brunt of the conflict.

Of all the branches of medical science, therapeutics is to the general practitioner of paramount importance. It is his buckler and shie'd; his lance and sword. It is his means of combating disease; his key to public confidence; the bridge which is to carry him to success or failure. This being his position in relation to the subject in question, it behooves him when this his chief citadel is attacked, to examine his intrenchments in order that should any defects be found, they may be remedied and his position strengthened.

No one will undertake to argue that this branch of the science of medicine is as exact as mathematics for example.

We cannot say that given a malady, and given a remedy, the one can be applied to the other with the same certainty of result that sulphuric acid applied to zinc will yield hydrogen gas.

To say, however, that therapeutics with all the principles which it teaches is a delusion, is virtually another way of saying that the physician is an imposter. We can not believe the one without admitting the other. The medical man, therefore, who stands upon the ground of extreme skepticism as to the question of the

*Read before the Monmouth Co., N. J., Medical Society, May 21, 1894.

treatment of disease, simply has no excuse for his existence; he puts himself upon trial for his life.

In contradistinction to the true science of our profession Trousseau has aptly called therapeutics the art of medicine; for as the mechanic's knowledge of the use of his tools is his means of carrying out his plans so is his knowledge of this art, the physician's means to a similar end. He may use the stethescope, the sphygmograph, the speculum, the urinometer, or any of the various instruments employed for precission in diagnosis, with the greatest possible skill, or he may with scalpel and microscope solve the post mortem problems which are placed before him; but his true function is to battle with and conquer disease, to face emergencies, and relieve physical distress; and this he must do, through his knowledge of the practical rather than the theoretical side of medical science.

If it could be demonstrated that the laws of health and disease were as certain in their action as the laws which govern the moments of the celestial bodies, or the laws of chemical reaction or as any other fixed physical laws, the art of therapeutics would soon become a science exact enough to please the most exacting. But unfortunately for various reasons this can not be accomplished; and the failure of therapeutics to maintain itself on the principle of quad erat demonstrandum has been unavoidably the means of dividing the profession into two great classes.

First:—The physician *par excellence*: the man who recognizing the importance of the fact that a medical man should be well informed in a general way, that he should appreciate the importance of a knowledge of the science of medicine, also knows it to be equally desirable that he should be a consciencious and skillful practitioner; and he knows that it is quite within the possibilities to be the one without being the other. His armamentarum is not extensive. He employs only those measures which he has found to be worthy of his confidence, and if he adopts a new agent of therapy, it must come to his notice very well recommended. He is conservative in the sense that conservatism does not interfere with progress. As his experience increases, so increases his usefulness. Each day in his busy life has marked an epoch in his accumulation of practical knowledge. Each day has made his weapons of offense and defense sharper and more available in that warfare in which he is so constantly employed.

Second:—The skeptic: This class is represented by the man who has a lofty idea that he only has talked face to face with Truth, has held her by the hand and enjoyed her utmost confidence. He takes the ground of extreme incredulity. He repudiates the entire system. He practices medicine because there is nothing else for him to do, trusts to the recuperative powers of Nature and sits quietly down and waits. If, however, his goddess smiles upon him, as she has occasionally been known to do, he coolly pockets his fee just as if he had something to do with the result himself.

Another class might be added, viz:—The empiric. The man who does not know the why or the wherefore, and does not care to learn. He generally employs the quassi proprietary concoctions that are sown broadcast over the land, and reads with avidity the accompanying pamphlets which describe in glowing terms the wonderful results obtained from this or that uterine alterative or nervine. Thus it may readily be seen that in our search for the factors which are causes for the elusiveness of the principles of therapeutics, the first fact confronts us is that as the perfection of a piece of mechanical work will vary with the man who uses the saw and plane, the square and plumb, so also will the results of the practice of our art, sometimes vary with the person who directs the remedies and agents in their application to disease. Another of the causes which may lead to disappointment in therapeutics is the failure of the medical man to recognize the difference in the susceptibility to drugs which obtains in different individuals. A resume of some well known facts in this connection, perhaps, would not be out of place. For example, I know a man who is influenced by one-sixteenth of a grain of morphia sulphate as much as the average human being is by one-quarter of a grain; and until this was discovered it was supposed he could not take the drug with safety. Another patient, a woman, who came under my notice after the administration of one-half a grain of morphia hypodermically, became comatose, pupils contracted and respirations ran down to four per minute; her condition was cer-

tainly one of extreme gravity, and was the cause of much anxiety on the part of her medical attendant. I am glad to say however that the patient recovered. Every physician knows that no definite law can be formulated as to the amount of quinine which will be necessary to break the paroxysms of intermittent fever, and yet we all know that if this drug is exhibited judiciously the result can be counted upon with almost mathematical certainty. So also in the use of bichloride of mercury and potassium iodide for the treatment of syphilis; who can say in a given case to what extent these agents will have to be carried and yet we know them to be worthy of our confidence. Chloral Hydrate, the bromides, sulfonal, and many other hypnotics are notably varying in their effects upon different individuals, yet these drugs seldom disappoint us when the proper dose is found. Strychnia is a remedy which has proved itself simply invaluable in various abnormal conditions of the heart, notably in valvular disease with a feeble systole and general lowering of blood pressure. In a rather extended experience with this drug in this class of cases, I have found the most varying susceptibility, necessitating the employment of doses of different sizes in order to obtain the result desired.

As in different individuals we find different degrees of sensitiveness to the effects of drugs, so also do we find that to produce certain results entirely different remedies will be required in different cases. Because tr. chloride of iron was beneficial in the case of A, who was anæmic, is no reason why it should be the most advantagious remedy for B.; perhaps iron by hydrogen or the sulphate, or the Pyrophosphate, or some other form of iron would act much more satisfactorily in the latter case.

Digitalis, the usefulness of which as a remedy cannot be questioned, can sometimes with profit be superceeded by convalaria; this fact is most pronounced in those cases in which digitalis is not well borne by an irritable stomach; convalaria is frequently much better tolerated. Nitro-glycerin and strophanthus which can be employed with advantage in many cases are plainly far from being satisfactory in others. The value of resorcin in the treatment of various gastric disorders, notably in chronic gastritis was first pointed out by Dr. Mackay in a paper read before the British Medical Association, in August 1886, and later by Dr. Wm. H. Thompson, in a paper read at the annual meeting of the New York County Medical Society, in November, 1892. This drug is certainly a most valuable agent, but an occasional case will be found where by its employment no appreciable effect can be produced. Dr. Thompson himself claims out of seventy-eight cases, fifty-one successes, twenty-one failures and six doubtful.

Out of fifteen cases treated by myself with this drug, which cases included gastric catarrh and acute and chronic catarrhal derangements of the small intestines, I can justly claim two-thirds of bona fide cures.

Necessarily a certain amount of experimentation will occasionally have to be indulged in, that the best means to an end may be found. The physician, however, should be quick to read the signs as to whether he is doing his best for his patient, and judiciously change his remedies when he thinks it can be done with advantage.

One point which will bear mentioning is the too general practice of prescribing drugs with no clear idea as to what is expected of them. Perhaps the hurry of a busy professional life, or the fear that the patient will demand that something be done for him, or the wish to gain time to study the case, or habitual carelessness, or even gross ignorance on the part of the medical man, will be the cause of a habit of loose prescribing; that is to say, with no conception as to the meaning of the symptoms presented, or at the most with only a hazy idea of a diagnosis, remedial measure will be recommended, and a line of treatment instituted with not the faintest conception as to what is to be accomplished, but only a fond hope that by a hit or miss process, a satisfactory result will somehow be obtained. Hence if the physician can not lucidly explain to himself *why* a remedy is given, it had much better not be given at all; or if he must prescribe on these lines, let him for the credit of his art, embrace the theory of high potency, so that his remedies may at least do no harm. Again the personality of the patient may sometimes be the cause of failure in therapeusis. This may be owing to impatience, to vacillation, or to a want of frankness, or

to stupidity in stating the case for consideration. A patient who is markedly neurasthenic will sometimes by a combination of these characteristics, make the life of his medical man a burden to him. There seems to be an undefinable antagonism between a physician and an occasional patient which influences to a marked degree the desired result. Perhaps this statement verges on the visionary, but such a condition I am sure not infrequently occurs.

One of the most important causes for the comparatively slow advancement of therapeutics lies in the fact that other branches of medicine promise more eclat to their disciples. The specialties demand larger fees and insure more public prominence. Surgery in all its special departments is notably alluring to the ambitious medical man. There is something which approaches the heroic in handling glittering knives and causing blood to flow. The every day experiences, the routine work of the general practitioner is a part of a life of usefulness, but it lacks the luster and stir, the applause and rewards of the other departments, and therefore while the science of medicine has enjoyed the advantage of having its achievements constantly recorded and heralded to an expectant world, the more unostentatious triumphs in the realm of true therapeutics have often represented the unrecorded private knowledge of individuals, the personal experience of quiet practitioners which passed into oblivion when the possessor ceased to exist.

Thus I have tried to demonstrate briefly, that while victory does not always perch upon our banner, it is not necessarily because therapeutics is a delusion and a snare, but because the art is continually hampered by conditions which tend to prevent its substantial advancement.

If I have underestimated the *science* of medicine, its institutes, its theories, it has been unintentional; for to not fully appreciate that which has rescued the profession from the darkness of superstition, would be virtually a confession of stupidity. Fothergill has said, "That some should declaim against theory, is no more than that an eunuch should inveigh against lechery; it is the chastity of impotence." The science of medicine is the foundation upon which the art must rest; and the foundation must be improved and strengthened in order to securely support the superstructure.

But let us not neglect the part of the building which is above the ground; the part which must be as a refuge to those who expect us to aid them. They do not see the solid masses of masonry, the iron girders, the braces and general perfection of the subterranean portion, but they judge of the entire building by the part which meets their view.

They do not estimate their medical man by any such standard as his knowledge of the pathology and remote consequences of regurgitation at the inetral orifice, but if by a possession of this knowledge, he is the better enabled to bring to them relief, then is he exhibiting attributes which they can fully comprehend and appreciate.

That the art has fallen behind the science in the struggle towards perfection, is manifest to any careful observer; and with the general practitioner, more than with the specialist, rests the future of therapeutics. With the country practitioner, perhaps, most of all, the man who has been scornfully called the cross-roads doctor, lies the power of retaining the art in a position of public confidence and trust. Because he must be a man of expedients; he must face emergencies of every grade, often single handed, and entirely cut off from professional council and assistance. He learns to choose his therapeutic measures with judgment, for he must have only those in his armamentarum which can be used with precision and profit.

He can also afford to be honest with his patients. Not being surrounded by the bustle and professional rivalry of the large cities he can advise them carefully and candidly as what is to their best interest, and not as is the fashion of the hour, place them on his medical Pegasus and fly with them through mystical labyrinths of gynecology, neurology and several other learned ologies, representing the entire internal and external structure of the human organism.

And as to Nazareth was once given the key to an important crisis in human affairs, so also may truth which occasionally lurks in strange places, some time in the golden future be found to have existed during all these years even in places remote from the hallowed precincts of the great medical centers.

PATHOLOGY OF CANCER.*

H. E. MUNN, M. D.,† Toledo, Ohio.

The essential histological elements of cancer consist of various forms of cells of epithelial character. These cells constitute larger or smaller spherical or elongated masses in the alveolar or interstitial spaces of the part in which they grow. Accompanying the growth of these cells and the continuous penetration of them into such spaces, is an increase, more or less proportionate, of the fibrous tissue stroma.

In many cases the new tissue is evidently an inflammatory hyperplasia produced by the irritating invasion of the epithelium. In other cases or forms, the stroma and vessels therein appear to be of new embryonic formation, and while not of due proportion, as in surrounding tissues, yet not bearing evidence of inflammatory origin.

Medullary encephaloid and the glandular varieties belonging to this latter group, and scirrhous and epithelioma to the former. The cells filling the alveoli, to a greater or less degree, resemble normal epithelial forms found on such surfaces, or in such masses where the growth originated. Conditions of rapid growth, of age, of degenerative changes and of pressure, determines the shape, size and other attributes of the cells.

If the theory, or rather hypothesis of Cohnheim, that tumors arise from the inclusion of embryonic cells or collections of cells, which after complete evolution of the tissues are by some stimulus excited to growth and development, unrestrained and undirected by co-ordinate or co-operative growth and development of the whole, —if this be true, and it seems not improbable, then the embryonic cells or bits of tissue from which the carcinomata arise, must have undergone evolution up to the stage of differentiation of the germinal layers. In fact, this must be true also of all tumor pathogenesis except perhaps for the so-called "dermoid cysts."

For leaving out these last, we find no abstractly heterologous tumors; but, those of mesoblastic character taking rise from tissue of mesoblastic origin, and the epithelial form hypo and epiblastic sites only.

What a matter of interest, perhaps of conjecture only, to look down along the path of tissue evolution, and see where nature's emigration train has, unnoticed, dropped the undeveloped, imperfect seed here and there along the way, to lie unseen, perchance to spring into luxuriant and noxious growth long afterwards.

Away down in the scale of development, probably from among the mass of cells having common and undifferentiated potencies, before the germinal layers had begun to form, was left aside from the current of evolution's tide, a cell or two, from these we get all sorts of tissues, epithelial and mesoblastic, in the "dermoid cyst."

Further up where the ways divide, we have the separation into three classes of cells, and across the line our growth cannot pass, but just this side of the line we have those abandoned orphans of nature who have all the possibilities of the mesoblast in its infancy. Here the sarcomata spring up; and so on, coming down to those which must have been passed by just before the final completion of tissue, to give rise to tumors much like normal forms. Curiously enough, we get no true nervous tissue tumor growth except in "dermoids" and the sustentacular tissue neuroglair gliomata.

So, these cancerous tumors also show their ancestral traits, for not only do they arise from epithelial structures solely, but they exhibit in morphology a similarity, more or less distinctly expressed, to the epithelium of the organ or surface in which their parent cell was included. Thus, the epitheliomata of epidermic origin have more or less aquamous cells, as also the more massive and even semi-columnar ones, which show degenerative changes similar to stratum corneum, lucidum and the malpighian layer. Cells like those in concentric nests and "pearls," staining like similar cells in stratum lucidum and corneum.

Those of internal passages of hypoblastic derivation have cells of columnar form with other distorted shapes. So also those of glandular site, present forms similar to

*Read before the Northwestern Ohio Medical Association at Van Wert, Ohio, June 29th, 1894.

†Professor of Histology and Pathology in Toledo Medical College.

those of the mature gland, or to those of general embryonic gland forms.

The development of normal cells, from the óösperm through all its progeny up to the fully matured individual living organism show a purposive tendency, a disposition even through many metamorphoses to arrive at definite and orderly complexity and differentiation. And, if abortive and monstrous forms occur, they are from interrupted and incomplete development, or some diversion of evolution into long obsolete but primeval paths. That is to say, however diverse the outcome of development may be, from that which now constitutes the complete and perfected structures or organism, the resultant parts or whole, show the attempt of the injured, hindered or exuberant cell to develop along the lines, and to the ends shaped by ancestral environment.

Therefore, we are justified in believing that these pathological forms are attempts of the aroused embryonic cell (hitherto latent), to produce something which it might have completed, had it gone on in tissue construction aided and restrained by its fellows.

Of epithelial tumor construction we have at the extreme two classes, one which is nearer maturity in embryonic ancestry, and, therefore, the main line—the benign adenomata, which frequently in its more perfect forms, rather closely resembles normal glands in structure and function—that is, producing something resembling some of the glandular secretions.

These may be set down as the epithelial analogues of the more mature varieties of mesoblastic tumor formation—the benign fibro-lipo-, chondro-, osteo-, myomata, etc. At the other extreme are the carcinomata; these are for the most part made up, as previously stated, of masses of epithelioid cells, penetrating into the subjacent tissues.

These may be classed as of the "cadet," line, which left the train of evolution farther back, and not having received the directing and restraining impress of orderly development and association as late as the other class, produce more aberrant forms. These are analogous to the malignant mesoblastic tumors—those embryonic and immature-featured sarcomata.

In the sarcomata we recognize the mesoblastic tissue tendencies, as much as in those of maturer and more stable development. So it seems to me we may recognize in the carcinomata the tendency of gland production, even though lacking most essentials of the adult organs.

Epiblastic glands are developed by the ingrowth of solid cylinders of epithelial cells, which branch and ramify, or remain more simple, with formation of lumen in ducts and acini by separation or degenerative solution and mingling in first secretion, further there is formed the specialized limiting basement membrane, continuous with that which lies beneath the malpighian layer, and upon the vascular corium.

In hypoblastic gland evolution, in some cases the same process obtains, but many of the glands are produced by tubular involutions of the mesenteron with subsequent specialization of cells into gland epithelium.

These invaginations may remain as simple tubular glands or become complex. The adenomata originate in the same manner, and some of them having lumina with cystic exaggeration, while others persist as solid cylinders of epithelium.

As before said, the more perfect the approximation to normal type, the more benign their characteristics. But these epithelial new growths are not all benign, many of them having a distinctly glandular appearance, being quite malignant.

Now, these go over toward the border line of carcinomata, and not only is there a shading off of the adenomata and carcinomata toward each other in qualities, but also in optical appearances.

And this insensible graduation goes on clear through the epithelial tumor growths, from one extreme to the other. At the extreme of carcinomata, we have an attempt at the production of gland tissue, but it reaches only the earlier embryonic stage in that line of evolution, that is, the ingrowth of epithelial or epitheloid cells in alveolar or cylindrical masses, without orderly arrangement, the formation of lumen or membrana propria.

While the most embryonic of sarcomas, those consisting of granulation cell elements, are recognized as abortive attempts at connective tissue construction, these epithelial ingrowths have been classed as "anomalous" instead of being denominated as of the type of "embryonic adenomatous tissue" tumors. For such they properly should be.

The general arrangement of cancerous growths and the cell peculiarities have, without a doubt, something of ontogenous impress; that is, are influenced in this way by the characteristics of contiguous structures. We see this quite markedly in the sarcomata, which take on pigmentary, or reticular, or alveolar form, if growing near or into structures having these qualities. Nevertheless, the phylogenous influence, or that of ancestral cell acquirement is the major one, for these growths never pass over the line which has differentiated the mesoblastic from the epithelial, thus exemplifying the laws of the "instability of the homogeneous" and "of increasing heterogenity" long ago recognized by Von Baer and Herbert Spencer. For though we find many examples of tumors taking on appearances in greater or less mimicry of contiguous tissues, we have every year more convincing evidence that the invasion of tumors by peripheral extension or embolic implantation in tissues of a specifically different class, has no effect to render its histogenesis other than that produced by that of ancestral or phylogenous impress.

The primary site of cancer, remote from some glandular structure, is in the nature of things almost an impossibility, except perhaps, those arising from the so-called endothelial surfaces of the serous body-cavities. So that the phylogenous influences in cancer are not so readily distinguishable from those strictly ontogenous.

In tumors of mesoblastic type it is, in very many cases, much more readily observed, for while many are decidedly homeotopic and heterotopic forms are perhaps quite as frequent.

The lymph-adenomatous structure, and the pigmented varieties of sarcomata, when originating in or near normal tissues having such features, are undoubted examples of local influence. Growths of fat, fibrous tissue, muscle, etc., in like normal tissue sites, are probably examples of late developmental interruption of the cells of origin.

Hererotopic growths as of bone, cartilage, fat and muscle, whether benign (and therefore of more mature type), or malignant, (and therefore more embryonic) necessarily must be interpreted as exhibiting some directing influence other than that of contiguous normal tissues.

Microscopical investigations in histology, embryology, and pathology, have demonstrated that in pathogenesis, as in normal histogenesis, there is, we may say, a determinate effort toward orderly and definite development. But the immediate cell ancestors of cancer growth, as of other neoplasms, lack the restraining and co-ordinating impress of the later stages of tissue evolution. The necessary exuberance, of growth and deficient stability, as well as the time of appearance, verifying for this much at least, the aphorism of Virchow, that "disease processes consist in excess, or deficiency, or being at the wrong time, or the wrong place."

The Value of Boiled Milk as an Article of Diet.

Every practitioner of medicine knows that in the treatment of certain cases of diarrhœa, where an absolute milk diet is required better results follow the use of boiled milk than of raw milk, and for this reason it has become a popular idea among the laity and members of the profession that cooked milk is the more digestible. However this may be in clinical experience, it is certain that experimental research dose not justify this conclusion. Ten years ago the late Dr. Randolph, of Philadelphia, made an interesting series of experiments to determine this point. A number of men in perfect heath were given raw milk to drink; an equal number, equally healthy, were given a similar quantity of boiled milk. An equal time after the ingestion of the liquid a hypodemic injection of apomorphine was administered to each, and a careful examination made of the vomited matters to determine how far the process of digestion had proceeded. In every instance it was found that the raw milk was more digested than the cooked, and as Randolph grahpically expressed it, "We obtained proof that in making milk, nature made that compound most easy of digestion."

The experiments of Crolas on the other hand, seem to point to a different result, for he believes as a result of his studies that boiling has no action whatever on the casein or lactose, and removes from the liquid a small quantity of butter, which is entangled with the film of albumin which forms on the surface of the milk. He also thinks that boiling increases the quantity of the free soluble phosphates, and concludes, in opposition to the studies of Randolph, that boiled milk is equivalent, if not superior, to raw milk.

CHRONIC OTORRHŒA—ITS SIGNIFICANCE AND TREATMENT.

DUNBAR ROY, A. B., M. D., ATLANTA, GA. *

Some one has said that the eye is "the window of the soul." and I feel justified in extending the metaphor by saying that the organ of hearing is the portal to our most sentient nature, It is true that the eye makes us cognizant of the beauties of nature—its mountains, its vales—its rivulets and oceans—its Autumn leaves with their myriads of tints, but it is equally true that the organ of hearing puts us into communication with the outer world by a sense even so subtle as that of sight; it causes a weird trance of immagination, filling the soul often with the sublimest ecstasy, causing us to burst forth in admiration for the words of the imortal Poet who said,

> "The man who hath no music in his soul
> Nor is not moved by concord of sweet sound
> Is fit for treason, strategem and spoils."

How necessary is it then, not only from a sentimental view as the above but also from one more practical, that we should endeavor by proper hygienic measures and, as far as possible, by the proper treatment, to preserve the integrity of the organ of hearing.

My object in presenting this paper is not for the purpose of going into the intricate pathology of this morbid process nor to bring forward any new and startling facts in its treatment, but in a practical manner to refresh the minds of those whose privilege it has not been to keep pace with the rapid advances of otology, and, at the same time, to incorporate some ideas gained from personal clinical experiences.

Otorrhœa etymologically means a discharge from the ear, but by common acceptation of the term it is usually understood as referring to a chronic running from the external auditory meatus dependent upon a morbid state of the tympanic cavity. Every discharge from the ear has its source and its distinctive cause which must be thoroughly ascertained before one can ever hope to treat successfully this class of troubles, for he who uses ear douches at random, or swabs out the ear in the same manner will often come to grief, and such can never hope to rise to that prominence in his chosen profession which comes by exactness and knowledge of the subject, coupled with a large amount of common sense. In teaching at the Southern Medical College my habit has been to divide all chronic discharges from the ear as having their origin either in the external or middle ear.

CHRONIC DISCHARGES FROM THE EXTERNAL AUDITORY MEATUS.

(*a*) Discharges which usually occur in some portion of the human economy arise almost without exception from cavities lined by mucous membranes, and hence it looks quite anomalous that a discharge should arise from the external auditory canal which is nothing but a dermoid surface. That such is the case no one can doubt who has ever had much clinical work in ear diseases. Sir Joseph Toynbee, in his work on Diseases of the Ear, published in 1860, enumerates many cases of pathological conditions of the external canal where one of its most common symptoms is a discharge from these parts. Sebaceous, sweat and ceruminous glands are abundantly scattered in the dermoid layer of the canal and there only needs an irritative factor in any form to produce a hyperæmia and congestion of the parts to be followed by a milky discharge. One of the most frequent causes of this symptom is is a moist eczema of the canal and closely allied to the same, as far as treatment is concerned, is the pathological condition known as otymycosis, depending upon the presence of certain parasites for the production of this morbid state. The symptoms of the two conditions are much the same. On looking into the external auditory canal one will observe a wet, soggy condition of the parts, flakes of moistoned epithelium like blotting paper clinging to the walls and in addition, a turbid discharge exuding from the canal. Such a condition is not infrequently met with, hence it behooves the physician to be ever on the alert for the true diagnosis, since by the proper applications the parts can soon be restored to their normal condition.

The treatment consists in syringing the canal at the first sitting with a warm solution of biborate of soda, cleaning the canal with a small curette, drying thoroughly the parts with cotton and then ap-

* Professor Ophthalmology and Otology in Southern Medical College.

plying your medicament. This latter is best done by ointments or powders. One of the best is a dram from each of Boric and Salicylic acid to half an ounce of vaseline. This should be applied once a day, to be followed by insufflations of Boric acid powder. With the subsidence of the symptoms the number of applications can be gradually decreased.

(*b*) *Polypi and Foreign Bodies.*

By the presence of such bodies as these the whole canal through irritation, becomes congested and with this hyperæmic condition there is an increase of the glandular secretion in this part. The discharge is sometimes very copious but differs from that which comes from the tympanic cavity in being more watery and whitish in appearance.

The only treatment in such cases as these is the removal of all foreign and offending substances. Polypi are best removed with the cold wire snare and their base afterwards treated with chronic acid applications. If the growth is too small for the snare, then a small ring curette can be used.

DISCHARGES ORIGINATING FROM AND DEPENDENT UPON PATHOLOGICAL CONDITIONS OF THE MIDDLE EAR OR ITS CONTIGUOUS CAVITIES.

Let us refresh ourselves for a moment with the anatomy of the parts. The tympanic cavity is situated within the hardest bone of the body, communicating with the throat through the eustachion tube, with the antrum mastoideus through the aditus antrum, while its outer wall is limited by the membrana tympani. It is lined throughout by mucus membrane, being continuous with that of the communicating cavities, and is traversed by a chain of three small ossicles. Two of these ossicles, the malleus and incus, are in close contact with the inner surface of the drum membrane, while the greater portion of their heads and bodies are situated high up in the atic of the tympanum. It is these two ossicles which have taken such a prominent part for the last few years in producing chronic discharges which had remained incurable until the necrosed ossicles had been entirely removed. Every case of chronic middle ear discharge can trace its origin to an acute otitis media, but why some of these acute cases recover without any untoward result while others leave their mark in the shape of a chronic discharge, are questions which have not been satisfactorily answered. Certain it is that the condition of the general system, the question of blood and lymphatic dyscrasiæ play an important *rôle*. We must also bear in mind the fact that a chronic discharge from the tympanic cavity can be either *simple* or *purulent* in character, and in this way greatly influencing us in our prognosis.

For convenience sake, I have classified chronic discharges from the middle ear as occurring in (1) Childhood, (2) Adults.

CAUSES.

(*a*) Children in whom there is a scrofulous or syphilitic taint are the ones most liable to chronic discharges from the ear, discharges from the nose, and to certain forms of ocular troubles, such as phlyctenular and interstitial keratitis. It is just in these cases that the systematic constitutional treatment produces its most beneficial results.

(*b*) The acute infections and contagious diseases, especially scarlet fever and measles, are frequently followed by a chronic otorrhœa as one of their sequelæ. In fact, statistics show that the majority of patients who suffer with a chronic discharge from the ear can trace its origin to an attack of measles or scarlet fever.

(*c*) Post-nasal adenoids, enlarged tonsils and chronic naso-pharyngeal catarrh are frequent causes and exciting agents in keeping up this condition through the connection of the middle ear and pharynx by means of the eustachian tube.

Most frequently adult patients who suffer with a chronic otorrhœa from the tympanic cavity, can trace its origin to some period of their childhood. That the same factors which acted as causes in childhood may also exist later in life is evident, but on account of the enlarging of the various parts and the greater power of resistence in the tissues of the adult, they are not so liable to the same disturbing influences. It is equally true that a certain amount of pathological condition existing in the naso-pharynx, in the way of adenoids, hypertrophies, chronic catarrh, etc., will not always answer as the cause of a chronic middle ear discharge, and we must look for some inherent condition existing in the middle ear itself as a cause for the persis-

tency of the discharge. I have frequently seen all pathological conditions of the naso-pharynx relieved and yet therewould persist an occasional discharge from the ear. That there is a close relationship, however, existing between these parts, all must admit, and he who ignores the nasal and naco-pharyngeal morbid states will never make a successful otologist.

When a chronic catarrhal condition of the middle ear has existed for some time, the mucous membrane and its contiguous parts are apt to be transformed into such a pathological state as to be themselves the exciting cause of the same. When we remember that, with the exception of the outer wall, the middle ear is a cavity enclosed in hard bone, and the nutrition of its lining mucous membrane is very easily interfered with, we are not surprised at the pathological conditions which we often find.

Among the first must be mentioned granulations upon the mucous membrane, which, as long as they exist will be a source for the production of a chronic discharge. Almost without exception in a chronic middle-ear catarrh there exists a perforation of the drum membrane, through which the discharge escapes; otherwise its only exit would be through the aditus ad antrum, or through the thin plate of bone which separates the tympanum from the brain,—a result, not, as Shakespeare says, "devoutly to be wished." Now with this secretion in the tympanum, it matters little how bland it is, one readily sees what a ready entrance is afforded to the various micrococci which will convert it into a purulent form.

Next in frequency must be mentioned polypi springing from the mucous membrane of the middle ear. These abnormal growths may be so small as to resemble granulations, or they may be so large as to protrude from the external auditory meatus. Usually they are by no means limited to one variety. Finally, a cause which of late has been recognized by otologists, as playing a prominent part in persistent purulent discharges from the tympanic cavity. This consists in a necrosis of some part of the bony walls of the tympanum, or of the chain of ossicles traversing the same.

TREATMENT.

Painstaking research into the history of every case; the correlation and comparison of all phenomena; a thorough knowledge of the normal and abnormal appearances of the parts, coupled with sufficient clinical experience, are necessary for the successful treatment of all ear diseases. Though but an atom as compared with the whole human frame, the field of otology is broadening every day, while the literature upon the ear alone would nearly fill an ordinary book-case. Certainly there is no brighter outlook in all the realm of medicine than is shown in the advances made in the surgery of the middle ear. While there may be extremists (they exist everywhere), yet with the conservatism which is being manifested and the large amount of clinical experience which is being added daily to the literature of the subject, we may hope for yet more brilliant results.

Every pathological condition must have its cause and, though we may not be always able to trace it, it is our duty and our professional gain to go thoroughly into the history of every case to determine, if possible, its *fons et origio*. For instance, the large majority of children who suffer with a chronic otorrhœa are also afflicted with some constitutional dyscrasia, hence it is only by the combination of the internal and topical applications that we can hope to bring about the most satisfactory results.

It is not my purpose to discuss the internal medication, for that can properly be left to the good judgment of every physician, but to go into the local management of these chronic discharges from the middle ear. Were I limited to one word as the foundation stone for the successful treatment of this class of diseases, it would be, *cleanliness*. Every secretion which remains blocked up in any cavity is a continual source of irritation and the cause of pathological changes, hence it should always be removed.

The treatment in children and in adults differs but little, save that in the former the parts are more delicate, smaller and, in some degree, less accessible. Whenever the discharge is active and very profuse, especially in children, the secretion must be frequently removed by syringing the ear with some antiseptic solution. The best in my hands has been a saturated solution of boraic acid. In very young children instruct the parents or nurse to use a soft rubber Davidson's ear syringe; in this way the parts will not be injured should the child grow obstreperous. The

physician himself should see the patient every other day, directing the nurse not to syringe the ear before coming to the office, in order that he may see any changes in the character and amount of the discharge. Having cleansed the ear himself by thoroughly syringing, the physician should dry the parts with cotton. If there exists a good-sized perforation in the drum membrane, the middle ear should be carefully inspected. In babies this is very difficult, so that occasionally one has to be content with the following procedure, which thus far has been eminently satisfactory to me. After syringing and drying the parts, the external canal is filled with pure listerine which is allowed to remain for five minutes, when the parts are again dried with cotton. The deep portion of the canal is now insufflated with powdered boraic acid, the canal packed with iodoform gauze, its inner extremity having been dipped into iodo-carbolized glycerine while its outer extremity is left accessible for removal by the nurse. The nurse is instructed to remove the packing as soon as it becomes saturated with the discharge, and to again use frequent syringings with the boric acid solution. This method of treatment is repeated every other day at first, and then at longer intervals. Having treated a number of chronic otorrhœas in children and babies by this procedure, I have found it by far the most successful in the large majority of cases.

In adults the parts are more accessible and likewise the pathological changes found more multiform. With this class of patients I find that the daily treatment by the physician himself, if possible, is much more successful, and the time much shortened, than by allowing the patient to carry on the treatment at home, which, in the large majority of cases, is very unsatisfactory. If the perforation is large and in the lower half of the drum, the line of treatment recommended for children can be successfully used in these cases. Frequently, however, the perforation exists in the upper part of the drum and is very small in size. In such cases it is usually found that the discharge comes from the attic of the middle ear, and for the successful removal of the same the solution must be introduced by means of a syringe or pipette of very slender and delicate proportions through the small opening in the drum.

As a rule, when there has been a discharge for years, the whole or the greater part of the drum membrane is entirely destroyed. In such cases there usually exists some pathological condition of the mucous membrane of the middle ear or some necrosis of the bony frame-work. Red, papillary granulations most frequently occur. These must be removed before one can hope to cure the discharge, as likewise must polypi, which, as a rule, are only overgrowth of the granulations. The best way to remove the former is by cutting, and the latter either by the cold snare or the ring curette. With the removal of these pathological growths the middle ear must be continually treated with the antiseptic powders, combined with tamponning of the auditory canal with iodo-carbolized gauze.

If, as often happens, the patient is of such a neurotic temperament that instrumental manipulation in the ear is out of the question, we may use what is termed the "alcohol treatment," instituted and recommended by Prof. Politzer, of Vienna. This consists in the instillation of absolute alcohol into the middle ear, allowing it to remain for ten minutes at a time, to be repeated, at first, two or three times daily, and gradually diminished. At first the patient may not be able to endure more than a 50 per cent. solution, but this can gradually be increased until the full strength is easily borne. I have seen most excellent results from this method of treatment, granulations disappear, polypi shrivel up and the whole ear reach a healthy state.

Finally comes a cause which of late has been found to play such a prominent part in keeping up a chronic discharge that has not yielded to the ordinary methods of treatment. This pathological condition is found to consist in a necrosis of some of the ossicles or of the bony walls of the middle ear, which, so long as it persists, will ever remain an exciting cause. Necrosis has been found most frequently in some portion of the malleus or incus, and since the greater parts of these ossicles lie in the attic of the tympanum, one more readily suspects such a pathological condition when the discharge comes through a small perforation in the upper part of the drum. The diagnosis of necrotic bone is ascertained by means of the probe, and when such is discovered there is but one course to pursue and that is the radical operation of removal.

COMMUNICATIONS.

CROUP AND DIPHTHERIA. *

B. H. DETWEILER, M. D., WILLIAMSPORT.

Mr. President, Ladies and Gentlemen: The pathology and treatment of membranous croup has been encroached upon by bacteriologists to such an extent that to is no longer considered a disease, *sui generis*, but only an exudate, the result in diphtheria caused by the Klebs-Loeffler bacillus. Dr. Wilson, in his exhaustive article on Laryngitis, in the Theory and Practice of Medicine, Pepper, 1894, says: "So overwhelming is the preponderance of the unquestionably diphtheric cases, that many competent observers regard all cases as that of nature—an extreme view that finds ample justification in the fact that no criteria have yet been established by which the differential diagnosis between diphtheritic pseudo-membranous laryngitis and the so-called non-contagious membranous croup of the dualist can be made by the clinician during life, or by the pathologist after death, save only by the presence or absence in the exudate of the Klebs-Loeffler bacillus. In both the symptoms are same, the course and termination of the attack are not different. "Physicians who look upon every case of pseudo-membranous laryngitis as a probable case of diphtheria, enjoy the practical advantage of erring; if err, they do upon the safe side."

The celebrated Drs. White and Keen, in their late surgery, endorse the same theory. Were the theory correct in practice, the course of the physician would be clear; but to the older physician the demonstration of the unity of these two diseases is not as yet complete. They are two distinct diseases; membranous croup was one of our terrible diseases, blanching the cheek of every mother upon the slightest whistling cough of her darlings, before the more dreaded name of diphtheria was a household word. In 1856, I saw my first case of membranous croup, and it proved fatal. In 1858, the first case of diphtheria came under my observation, which then became epidemic.

The course of these diseases was widely different, but when the larynx became involved, their termination was the same—death. Dr. O'Dwyer says that one child in ten, with well marked symptoms of laryngeal diphtheria recovers under medical treatment—Dr. Wilson says under all forms of treatment the mortality ranges from 60 to 80 per cent., and that all cases should be treated alike, as for diphtheria. It is the fact of this large mortality which I especially wish to press upon your consideration.

I do not consider it necessary to call your attention to the anatomical construction of the larynx, nor the distribution of the squamous epithelium upon the lining tissues of the pharynx and mouth, and the ciliated upon the vocal cords; nor that these epithelial cells determine whether the exudation be croupous or diphtheric. This is the point that should be fully considered, and upon which the duality of these diseases depends.

Dr. Wilson says, "ciliated exudation is termed croupous and squamous diphtheric; hence, the German pathologists, are correct in speaking of this process as a croupous diphtheric inflammation." Croupous inflammation is in all cases the exudation that involves the vocal cords from their anatomical construction, or ciliated instead of squamous epithelium. If this exudation be exposed to the Klebs-Loeffler bacillus, there is no question of the attack being diphtheria; but should it be simply inflammation of the vocal cords, why not treat it as any other inflammation? Why wait till the exudation becomes formed; if diphtheric, the mortality is so great that it is almost hopeless? and if not, why allow this exudate to become so firm that it is equally hopeless?

The cause of death is mechanical obstruction in one case, and in the other, mechanical obstruction with septic poisoning, due to specific microbes. The patient will be a croupy child—probably its second night with a harsh, rough cough and high fever. The preceeding night it

* Read before the Medical Society of the State of Pennsylvania, 1894.

had a few paroxysms of croup, was restless, with some fever; during the day it was apparently well. There is no exudation in the throat and nose, nor any enlarged cervical or submaxillary glands. This is a case of acute laryngitis of childhood; but in the morning you find instead of convalescence, a short hacking cough with continued fever, and you are not so sure of your diagnosis. If there are bacilli of Klebs-Loeffler in the trachea below the point of observation, the child will die; but if the thickening of the vocal cords by this croupous exudation is simply inflammatory, why not treat it as for inflammation?

Twelve hours will determine whether you can restore the child to its mother's arms or have it die the slow death of strangulation, or modified by the happy intubation of O'Dwyer with its record of decimation. It is cyanosed—breathing with the clavicular space indrawn and its throat clasped with its tiny hands to avert strangulation. You place two or three leeches on the larynx with ¼ grain doses of calomel every half hour till the characteristic spinach stools are voided; after full depletion of four or five hours, you check the bleeding points, apply a blister, and the cough will diminish, the cyanosis disappear, and in a couple of days the child will be convalescent.

During this treatment, inhalation of steam with lime water will be grateful and curative. The first case that I treated in this manner was in 1867. The distinguished physician who called me in consultation stated the case was hopeless, and said that the boy must die. He was two years old. As a dernier resort, I applied two leeches, and in five hours applied a blister. He convalesced rapidly. I have had many such cases in these years—one especially, when the consulting physician insisted on tracheotomy, but after depletion, neither intubation nor tracheotomy were required. Another, when I saw the boy of two years at 6 p. m. on the evening of the second day, after a croupy night. At 9 the same evening I found him cyanosed—and so much oppressed, they could not hold him in his crib. I applied two leeches, and followed it by a blister. In 48 hours he was convalescent.

Should this exudate, even, be diphtheria located below the point of observation, the child may recover, but will probably die—as the treatment beyond the abstraction of blood is what is considered proper by many who pride themselves on their success in treating this terribly fatal disease; but if it is not surely diphtheria, and there is a bare possibility of it being a croupous exudation on the vocal cords, why not use the depleting and revulsive treatment, instead of relying upon the treatment that has a standard mortality of 60 to 80 per cent., and rely upon removing the immediate danger of strangulation by intubation or trachetomy? I select my cases, and in doing so, have not lost a single case of membranous croup, nor have had an intubation.

My mortuary record of diphtheritic exudation extending into the larnyx, is no better than my compeers. I am persuaded it is of importance that the recognition of the duality of these diseases be made early, and that it is not good practice to err, if err they do, by treating all cases of croup on the so-called safe side of diphtheria with its terrible mortality record, and that it is the duty of every practitioner to diagnose *early* every case of croup; if diphtheritic, treat it accordingly; if membranous, give it the advantage of depletion and revulsives, by the prompt administration of calomel in quarter grain doses, every half hour, till the characteristic spinach stools are secured; inhalation of steam from lime water, which dissolves the croupous exudate upon the vocal cords, which causes the disease; and prompt depletion for four or five hours by leeching, and followed immediately by a cantharidal blister, which treatment will result in certain and speedy cure. Without the help of intubation or tracheotomy, I have followed this course since 1867 without the loss of a single patient.

EDITORIAL.

THE PHYSICIAN IN THE EYE OF THE LAW.

From the first appearance of the physician and surgeon's sign on his office front until he rounds out his professional career, he is confronted by embarrassments. The sense of the meagerness of his knowledge, and its inadequacy to meet and settle satisfactorily the many intricate and perplexing problems inseparable from his science and art, grows rather than diminishes with added experience. All his days are anxious days, the more anxious if he is fortunate in the possession of a quick, enlightened, professional conscience, feels and acts in his work as if it was something more than a mere vocation; a consecration to the gravest and most responsible form of life service, instead of being something routine and merely mechanical.

Not least of the embarrassments, annoyances and perils which continually threaten the physician and surgeon, no matter what his education, skill and eminence may be, nor the length of his successful professional services, is prosecution in law courts for malpractice. The prosecution may be in criminal form, or what passes under the misnomer of a *civil* suit —or both.

The criminal is the less frequent by reason of the difficulties and risks involved, and for the further reason that in such cases the commonwealth, in the name of public interest and safety, is made a party.

For those prosecuted for wilful mischief the profession has no sympathy. It is only by the strong hand of the law that impostors—those who usurp the honored title of physician or surgeon—can be weeded out, and the ignorant and innocent protected from the impostures of the quack.

With the civil suit the profession has most concern. These are much too common, and however they may result, are always damaging to their victim, causing loss of time, annoyance, the payment of heavy fees, and not infrequently the besmirching of a worthy and honored professional name. The motives usually behind and prompting these civil suits are malice and cupidity, and not infrequently can be seen the stealthy, filthy, cowardly

hand of one who masquerades under the title of physician and surgeon. We have before urged through these columns that these causeless prosecutions can be largely faced down by a united and healthy sentiment of common professional brotherhood. The great body of the profession has no reason to fear the severest judicial scrutiny of its work and its results.

Those who pass through our best technical schools, in education and skill measure up to the criterion judicially established. The law too, is progressive, keeps pace with changed conditions and wisely increases rather than relaxes its requirements.

The trend of the high court decisions is to force the profession to keep abreast with the advances in medical science and art.

One of the most learned and eminent of Pennsylvania's jurists, in a Supreme Court opinion, clearly defines the legal obligations of the profession. He says:— "The law has no allowance for quackery. It demands qualification in the profession practiced. Not extraordinary skill, such as only few men of rare genius and endowment possess, but that degree which ordinarily characterizes the profession. And in judging of this degree of skill in a given case, regard is to be had to the advanced state of the profession at the time. Discoveries in the natural sciences for the last half century have exerted a sensible influence on all the learned professions, but especially on that of medicine, where the circle of truths has been relatively much enlarged. And besides, there has been positive progress in that profession resulting from the studies, the experiments and the diversified practice of its profession. The patient is entitled to the benefit of these increased lights. The physician or surgeon who assumes to exercise the healing art is bound to be up to these improvements of the day. The standard of ordinary skill is on the advance, and he who would not be found wanting, must apply humbly with all diligence to the most accredited sources of knowledge."

This opinion must be recognized as sound in its logic. And, as expressed by an Associate Judge, "It is important to the interests of society that the profession intrusted with the preservation of the health and lives of the community should be held to a strict rule of accountability. Men of true science will not object to this. They court investigation. But the incompetent practitioner and the designing empiric 'love darkness rather than light,' and the sooner they are driven by judicial scrutiny into other pursuits for which they are better qualified and where they can do much less mischief, the better for the public welfare. But it is equally important that professional services should be fairly treated, and that the skill and worth receive the protection of the law."

From these decisions and others, the correct rule would appear to be that physicians and surgeons must keep abreast of the times, and make use of the latest and most improved methods and appliances, having regard to the locality and general practice of the profession.

The locality in which a physician or surgeon resides is to be taken into account. One practicing in a small town or sparcely settled country district, is not expected to exercise the care and skill of one residing in and having the opportunity afforded by a large city. He is bound to exercise the average degree of skill possessed by the profession in such localities generally.

These judicial conclusions are founded upon good reasoning. Physicians remote from cities, though well informed in theory, are seldom called upon to perform difficult operations in surgery, and do not enjoy the greater opportunities of daily observation and practice which large cities afford. So the standard of skill may differ according to circumstances and locality. But it must be noted that the

tendency of our courts generally is to elevate the standard of learning and skill required for the practice of medicine and surgery, and they are growing to instruct juries in estimating what qualifications are necessary to consider the average skill, learning and experience of the profession, properly so called—that is of well educated medical practitioners and exclusive of quacks and mountebanks.

If the physician has the skill and does not apply it, he is guilty of neglect. If he does not possess it, he is liable for want of it. The essence of the contract is that he is to do his best; to give to the use and service of his patient his best knowledge, skill and judgment; that he will use reasonable and ordinary care and diligence in the exercise of his skill and the application of his knowledge, to accomplish the purpose for which he is employed. He is not responsible for want of success in his treatment, unless it is proved to result from want of ordinary care, or ordinary skill and judgment. The degree of care to be required in cases varies with the character and exigencies of the cases. He does not contract for extraordinary care, or extraordinary diligence anymore than he does for uncommon skill. The words, reasonable and ordinary are judicially used as equivalent words, and applied in their common acceptation. In the implied contract to exert his skill and apply his diligence and care, he contracts to use his best judgment. He is, however, responsible for disregard of the well settled principles of medical science—he cannot interpose his own judgment to that which is settled except at his own peril. This dictum has been carried too far, however, by some of our courts. Many old forms and methods of treatment, both in medicine and surgery have been pushed aside by science and a more extended experience. Our knowledge has been greatly advanced by men devoting themselves to separate branches of the profession.

Precedent does not amount to so much in medicine and surgery, as in law. Medicine has less veneration for old and clumsy methods, effete formulas—for forms of treatment which, if not positively mischievous and dangerous, are useless. In medicine it is no longer as the fathers testified but as the best tests of science testify. Within the generation of which we are part, the profession has grown away from what was the practice and almost general law of the profession, that of reckless and indiscriminate bleeding; they no longer deny cooling drinks to fever patients, as was almost universally the case thirty years ago. It is fearful to contemplate what penalty the poor physician would have suffered who thirty years ago would have had the *ignorance, the want of skill and care,* or the temerity to experiment by giving a fever stricken law judge a glass of ice water.

There is yet another dictum laid down in court decisions which makes medical and surgical experiment penal and renders the physician and surgeon liable for civil damages. It would be interesting and of inestimable value to the profession to have some learned jurist define what constitutes *experiment* in medicine and surgery. There is not a drug prescribed, nor any form of applications of the knife that did not begin as an experiment. Everything, from Government down, that blesses civilized society, that heals, relieves suffering, mitigates hard human conditions, sustains human hope and enhances man's happiness had its beginning in experiment, not *reckless, but thoughtful, sober, rational experiment.*

The much that has been and is being accomplished by the medical and surgical profession is but feebly prophetic of the possible. The word is, *go on,* and the law will helpfully keep step. There are many matters, both in medicine and surgery yet to be determined by experiment, and the law will recognize that there is no larger

or more promising field of progress and one not to be bounded or limited by judical decision. The statute to be wise must always respond to human need.

All medical practice is based upon certain theories, these theories are constantly undergoing modifications under a changing and better light. Many an old hypothesis through the force of its absurdity has been pushed to the wall. The effort of modern teaching is to remove medical and surgical theories as far as possible from all error. In late years the changes in operative appliances and methods have been numerous, and both medicine and surgery have grown more and more to be affairs of science. The processes of this growth are infinite—the end will never be reached.

In general the law does not look upon the physician and surgeon with distrust or judge his work and its results with an illiberal spirit. The law recognizes the doubts and uncertainties which surround the medical and surgical practitioner, and that the errors and mistakes to which he is unavoidably exposed may well furnish a satisfactory explanation of unfavorable results, that cases of sickness and accident apparently similar, may yet be rendered substantially different by seemingly slight circumstances easily overlooked and sometimes of difficult detection.

In surgery, aside from the mere matters of manipulation or method, the courts recognize that a surgeon has to contend with very many powerful and hidden influences, such as the habits, hereditary tendencies, vital force, mental state, and local circumstances of the patient, it excuses errors of judgment when not so gross as to be inconsistent with reasonable skill and diligence.

Care is an important element in all cases, it implies the use of such watchfulness and precaution as is fairly commensurate with the danger to be avoided, judged by the standard of common prudence and experience. All will admit that the scrutiny of the law cannot be too severe where the issues of life and death are involved, but there should be justice to the physician—wisdom and an enlightened justice should hold the scales.

ABSTRACTS.

SOME REMARKS CONCERNING MERCURIC BROMIDE OF GOLD AND ARSENIC, WITH ESPECIAL REFERENCE TO ITS USE IN THE TREATMENT OF NEUROTIC CONDITIONS OF SPECIFIC ORIGIN.

[ABSTRACT]

THOMAS HUNT STUCKY, M. D.,* LOUISVILLE, KY.

At a recent meeting of this society, I had occasion to mention the use of the bromide of gold and arsenic in epilepsy. Being, comparatively speaking, a new drug to this market, it was thought of sufficient interest to bring it more prominently before the fellows.

The solution of mercuric bromide of gold and arsenic after the formula of Dr. Barclay, of Pittsburgh, is of a beautiful red color, does not deposit, odorless, and tasteless; dosage ranging from five to twenty drops, each drop containing 1.32 of a grain of gold, 1.16 of a grain of arsenic, and 1.32 of a grain of mercury salts. It does not disagree with the stomach, nor relax the bowels. It will produce ptyalism, yet with less recession

* Professor of Theory and Practice of Medicine and Clinical Med., Hospital College of Medicine.

of the gums than is produced by mercury or the iodides.

Dr. Wood, in his admirable paper, read at the meeting of the Mississippi Valley Medical Association, in Indianapolis, laid great stress upon its efficacy in diseases termed scleroses, incipient phthisis, arthritis deformans, in syphilitic diseases in its various forms, in hemiplegias, etc.

I have the pleasure of exhibiting three cases to-night, and a record of eight others, all of whom, with one exception, belong to the neuroses.

CASE 1.—No. 436 of my college clinical records; diagnosis hemiplegia. W. O. M. æt. 28, married; residence, Denver, Colorado; family history, fairly good; occupation, proprietor of theatre. Habits: had used alcoholic beverages rather freely for five years. February 28, 1893, following a two-days drunk, patient vomited with great straining; passed into unconsciousness lasting seventy-two hours; complete dextra-hemiplegia, ataxia, aphasia sinistra-hemiplegia supervened. December 2, 1893, patient presented himself at clinic, having complete paralysis of the right side, could not count fingers with left eye; tongue on protrusion, pointing sharply to the right; corners of the mouth greatly depressed on right side; arm on the right side could scarcely be lifted away from the body; leg dragged after the patient in characteristic manner; all reflexes greatly exaggerated. Patient could answer yes and no to questions, but could not tell where he lived, and had to be brought to the college. Was placed on liq. arsenic et hydrarg. iodide, five drops in a wine glass of water, after meals.

December 6th, was given the mercuric bromide of gold and arsenic in five drops, doses after meals.

December 9th, patient developed la grippe, treatment was discontinued, and acetanilide given.

December 13th, condition improved, and mercuric bromide of gold and arsenic was given again.

December 20th, some improvement, medicine continued.

January 3, 1894, dose increased to ten drops.

January 26th, patient answers all questions with comparative ease, came to the clinic by himself, can lift his arm as high as his shoulder, the characteristic tremor taking place when he attempts to raise it still higher, can walk tolerably well; treatment continued.

February 7th, continued improvement.

February 14th, eating and sleeping as good as before attack.

February 28th, steady improvement in gait and speech.

March 10th, doing well.

March 17th, dose increased one drop every other day.

March 21st, has regained self confidence.

April 4th, walks miles, does not have to use cane, no longer drags his foot. Secondary contraction of a slight degree has taken place in the fingers only. Students not familiar with the case could not detect any depression at an angle of the mouth. Sight in left eye much improved, though outer half is still impaired. Tongue points nearly in the median line. Patient steadily improving.

Case 2.—J. R. æt. 35, tobacconist; personal and family history good; he has never had syphilis nor rheumatism. His trouble began about eighteen months ago, with the characteristic pains in the lower extremities. These pains were felt at irregular intervals, sometimes daily and sometimes not for a space of a week or ten days. A short time afterward he noticed the change in gait. He also had frequent attacks of sick headache, three or four seminal emissions weekly, and difficulty in holding the urine. These symptoms ceased about four months ago, but the ataxia has greatly increased, and the pains still continue. He has noticed in the last three or four months a decline in the sexual power. He was admitted into the Hospital February 1st, 1894. The skin, reflexes and the knee jerk were normal; there were no sensory symptoms; he had the Argyll-Robertson pupil; coordination was so imperfect that he was unable to stand with the eyes closed, and the feet together; and he could hardly make his way from one place to another.

In treating this case I started February 28th, with eight drops of the mercuric bromide of gold and arsenic three times a day. From March 14th to April 1st, the dose was increased one drop each day. The total quantity given during thirty-three days being 1,245 drops, an average of thirteen drops at each dose.

Case 3.—W, P. æt. 32, painter; personal and family history good. His illness

dates back to February first, 1892, the symptoms being constipation, difficulty in voiding urine, stiffness and soreness in the knees. In a short time the legs became useless. In six weeks he was about on crutches, being at the time under treatment at Hot Springs. He entered the Hospital July 7th, 1892; at that time there was very little sensation in the left leg, the condition of the right being about normal. He had incontinence of urine and feces.

Commencing February 7th, I gave him five drops of the mercuric bromide of gold and arsenic after meals; the dose was increased daily until eleven drops were being given, making the average dose given during the course, of ten drops, thrice daily. Bladder and bowel symptoms restored.

Case 4.—Mr. S. (I will refer to this case briefly, not being able to get the patient to come here tonight.) There was loss of sensation in right side of face; difficulty in co-ordination; ptosis; chronic constipation; loss of bladder control; reflexes lost. Four months treatment followed by complete relief.

It could hardly be coincident that such decided changes for the better, should have occurred in so short a time.

There have been and are now many preparations on the market which are not solutions of bromide of gold and arsenic, but bromide of gold with hydrobromic acid, arsenic acid, and arsenious acid. In the Annual of the Universal Medical Sciences issue 1891, Dr. Hare in his article on Experimental Therapeutics concludes in reference to the action of bromide of gold:

(1) Bromide of gold undoubtedly inhibits the cortical motor centres, even when administered in small doses than other bromides. After an internal administration of bromide of gold in the dose of 1½, to 3, 1-10 grs. to the kilogramme of the animal's weight, even the strongest and very prolonged electric stimulation of the cortex fails to bring about any epileptic seizures. To obtain the same result from bromide of potassium, the latter should be introduced in the dose of 9½, to 10¾ grs. to kilogramme. While bromide of iodium should be given in still larger quantities.

(2) Irritability of individual motor centres as determined by the appearance of contractions in corresponding muscular groups is depressed by bromide of gold in but trifling degree.

(3) Excitability of the white substance of the motor region remains intact.

(4) The drug seems to affect mainly the tracts of communication between individual motor centres, as well as between remote areas of the cerebral cortex.

(5) It does not appear to possess any special cumulative action. This action cannot be due to the amount of bromide present therein, since it is in the weakest (55 per cent. by weight) of the three, white bromide of sodium is the heaviest (77.7 per cent.) the potassic salts standing midway.

In the Annual of the Universal Medical Sciences, year 1892, an authority states "Better results can probably be obtained if the drug be given hypodermatically."

The opinion as to the efficacy of gold in disease has been indeed varied: In an article Med. Rec. Vol. 34, page 802, September, 1888, this appears—referring to article on gold and arsenic—"It is highly digestible," while farther on this startling statement appears,—"There is probably not a sound clinical observation, showing that gold possesses any special therapeutic efficacy in any disease."

The old therapeutists limit its field of usefulness. Bartholow speaks most highly of it, recommending the double chloride in waning sexual force, in granular and fibrous kidney, in melancholia, in atonic dyspepsia, catarrh of bile ducts, etc. The claim made that it produces auric fever has not been observed, nor have I seen any evidences of gastric irritation. In a case of syphilitic nodules with marked cephalagia, there was a rapid subsidence of the nodes and relief of the head, by the mercuric bromide of gold and arsenic, proving clearly that there is a most decidedly alterative influence exerted.

The fact that the sedation produced by the bromide of gold is greater than that by the salts of potash and soda, should give it a front rank in the treatment of epilepsy, fortified by the alterative influence of the gold and the tonic effect of the arsenic. It has long been recognized that arsenic is the treatment for chorea. In three cases of this disease treated by bromide of gold and arsenic, the results were all that could be desired.

The solution of gold as prepared by Johnson & Johnson:

1st.—Increase the appetite.

2nd.—Do not irritate the stomach nor disturb the bowels, seeming to stimulate peristalsis without sufficient irritation to produce purgation.

3rd.—Do exert decided powers of alteration, sedation where there is irritation, yet stimulation to waning powers.

4th.—Are indicated in the majority of diseases affecting coördination.

5th.—In fact, entitled to a trial in all neuroses.

SOCIETY REPORTS.

LOUISVILLE MEDICO-CHIRURGICAL SOCIETY.

April 6, 1894.

[STENOGRAPHICALLY REPORTED BY C. C. MAPES.]

GALL-STONES.

DR. A. M. VANCE: I would like to show three or four little specimens of gall-stones removed from a woman twenty-six years of age with the history of acute pain, and beginning sepsis with a tumor low in the abdomen. The gall-bladder was found very much enlarged, filled with mucus and subsequently quite a quantity of pus came from the deeper parts of the sac. The diagnosis was not made absolutely before the incision, though after the woman was on the table the consensus of opinion of those present was that the trouble was the gall-bladder. I also show you several specimens from a patient operated upon some years ago. The case was similar to the one I have just reported, and my only object in mentioning it is to show the different character of the calculi.

I do not believe there were any gall-stones in the cystic duct, since excessive flow of bile has occurred so soon. The obstruction was probably inflammatory rather than from stones. A great deal of bile came away at the forty-eighth hour. The woman has made an uninterrupted convalescence.

DISCUSSION.

DR. WM. BAILEY: In the last case reported by Dr. Vance the difficulty in diagnosis was considerable I have no doubt; from the tension of the muscle on that side it was difficult to define, but after she was under the anæsthetic it was possible to make a more accurate conclusion as to where the tumor really was. However the incision on account of the uncertainty was a little high for the appendix and a little low for the gall bladder. It was really a compromise. If there had been a positive diagnosis the incision would have been properly made, and Dr. Vance could have more readily explored the opening of the cystic duct into the gall bladder, but from the position of the incision without enlarging it too much, he was not able to reach so as to thoroughly explore the cystic duct. I think it probable as Dr. Vance has said that the duct was closed by inflamatory processes and not by gall stones. The intensity of the pain was not such as to indicate the presence of gall stones in the cystic duct, but rather from an accumulation and inflamatory process that was going on in the gall bladder.

Dr. T. H. Stucky read a paper entitled:

SOME REMARKS CONCERNING MERCURIC BROMIDE OF GOLD AND ARSENIC, WITH ESPECIAL REFERENCE TO ITS USE IN THE TREATMENT NEUROTIC CONDITIONS OF SPECIFIC ORIGIN.

(See page 257).

DISCUSSION.

DR. A. M. VANCE: In the third case shown was there any history of lead colic?

DR. T. H. STUCKY: The patient gives no history of lead colic.

Dr. S. G. DABNEY: I saw the fourth case referred to by Dr. Stucky; there was complete paralysis of the motor oculi nerve. The gentleman of course had ptosis, and there was also some protrusion

of the eye ball. At the time I saw him there were also some symptoms of beginning locomotor ataxia not very marked at that time but perhaps developed later. I have no doubt the agent mentioned by Dr. Stucky is valuable in many cases, but I have in mind cases similar to those he reports that recovered under large doses of the iodides. Two were cases of complete paralysis of the motor oculi nerve which made a good recovery. One of them was a woman who also showed some symptoms of locomotor ataxia. I wish Dr. Stucky had been more explicit in his remarks concerning Hemianopia in the first case he reported. I presume it means half vision of each eye, i. e. one half the field of vision of each eye is lost.

Dr. Stucky will recall a case of this kind occurring in a lady that we saw some time ago, who had paralysis, and well-defined hemiopia. She finally recovered from the paralysis, but the half sight remained the same. Dr. Hays will also remember a similar case; the patient was a man who had no well-defined paralysis, but had a great many cerebral symptoms and a clearly defined case of hemiopia. The other symptoms have all gradually improved, but the half sight remains exactly as it was. This symptom of hemiopia may be due to disease of the optic nerve tract, or it may be due to a lesion of the cortex of the brain. As a rule it is not improved even when the other nervous symptoms disappear. When paralysis for instance disappears, the heminopia as a rule remains. It is not a frequent symptom and I think it rather peculiar that I have seen two or three cases in my experience in Louisville. I remember having heard one of the occulists here, whose experience is larger than mine, say that he had not seen a single one.

Dr. Wm. Cheatham: I think Dr. Stucky's cases are all too recent to show what effect his treatment is going to have, except in the third case where improvement has been so marked. I would not be inclined to attribute the improvement entirely to the remedy. Especially in locomotor ataxia it is about as uncertain as in epilepsy when you are going to have improvement, and whether this improvement comes from the remedy. I have seen cases where the eye muscles were involved in locomotor ataxia and the patients have gotten apparently well so far as the eyes are concerned without any treatment. We all know that locomotor ataxia has periods of rest, especially in the early stages of the disease and where the eye muscles only are involved, these cases often apparently completely recover without any treatment. I call to mind now the case of an army officer who afterward went east and I took him to see Dr. Hammond, also Dr. Knapp, who diagnosed locomotor ataxia. This man at one time went four years between attacks. He had double vision, and sometimes complete ptosis. He had specific, locomotor ataxia. The next attack came on in about two years, with complete ptosis of the left eye only. On account of these periods of rest it is as I stated before very hard to determine just what effect any remedy is going to have; therefore I think Dr. Stucky's cases are to recent to say positively that the medication is the cause. His report, however, is one of much interest.

Dr. Wm. Bailey: Dr. Stucky has presented us with an exceedingly interesting clinic, and I want to say moreover that I am gratified because it is in a department of therapeutics that has been very uncertain in its effects. Certainly the cases presented to-night with the history as detailed, should induce us to give the remedy a trial at any rate. I am sure that Dr. Cheatham is right as to the uncertainty of these cases, the progress and natural history of them is so marked even under the most thorough treatment. I have had a case of epilepsy on bromides without an attack for eighteen months and believed that the remedy did a great deal good; very much to my mortification he had an attack yesterday and one again to-day, notwithstanding he has been kept upon the bromides constantly. I am inclined to think from the presentation of the subject in the papers and by the discussion to-night, that I shall give the preparation of gold and arsenic a trial at the first opportunity. It certainly offers us something where we need much.

Dr. Wm. Cheatham: I have used the bromide of gold and arsenic in one case; the man has atrophy of both optic nerves and is also said to have syphilis. He has been on anti-syphilitic treatment, however, with no improvement. He took the gold, I think, three weeks, but there was no perceptible change. Vision is reduced to 6–200. He has also had two courses of strych[illegible]

nitrate hypodermatically, with no improvement.

DR. H. A. COTTELL: I am sorry that I came too late to hear the essay, but take it that the remarks of Drs. Bailey and Cheatham set forth the facts pretty clearly. Their experience is the common experience of every man who treats such cases—their issue is very uncertain. A case of locomotor ataxia came under my care four years ago. The patient went through the hands of several physicians, growing worse all the time and was finally forced to go to bed. He had lightening pains, which were so severe that he was kept under the influence of morphine for a considerable time. Although the case was non-syphilitic he had been given iodide of potassium, in fact, I believe, almost everything except the bromide of gold and arsenic. He finally went to Pennsylvania somewhere to see a priest who was said to work miracles. He was given a prescription of wine of cocoa and nitroglycerine and made a seemingly complete recovery, although to the practiced eye his gate is slightly ataxic.

I had another case in the person of a Jewish man—a well marked case of locomotor ataxia of syphilitic origin, at least such a history was elicited. This man seemed to be improving under iodide of potassium, and coming to me one day, he asked, if I thought it would do him good to go to the country. I told him I thought it would, if he would simply go there and rest, that he must not take much exercise. He went down in Breckinridge County, and while there fell in with an old fashioned German doctor, who told him that his disease was not locomotor ataxia, but simply inflammation of the spine. This doctor put him under treatment, applying poultices and plasters, and at the same time drugging him with herbs. The man grew rapidly worse, returned home, became bedridden, and, I believe, died. He was never able to get out of his bed after his trip to the country. What this country doctor did to make this patient grow so suddenly worse, I cannot understand. These two cases represent the two extreme conditions. We have all seen ataxic symptoms progress and diminish, oscillating between these two extremes. We see, however, many cases that have been moderately ataxic for years, and it is to be hoped that something has been found that will make an impression upon the lesions which lie behind the symptoms. One of the most discouraging things in the life of the specialist in nervous diseases, is that there is so little real therapy in the practice. In consequence of this the temptation to substitute quackery in this department for the principles of scientific medicine is great indeed. I am sorry to see that some eminent men in this country have found the temptation too much for them. If any remedy can be found that will make an impression upon scleroses, posterior, lateral or disseminated of non-syphilitic origin, we all shall hail it with delight. At the last International Medical Congress, Strümpfel read an able paper on scleroses, taking the ground that the only curable cases were those of syphilitic origin. I hope that the bromide of gold and arsenic is the remedy we have been looking for.

There is something very peculiar about the heavy metals like gold, platinum, etc. They have very little mechanical effect as we know. It has been found that chloroform will take more gold in the presence of nitric acid, so that all the double salts can be made—chloride of gold and sodium, bromide of gold and sodium, etc. They are chemically, I suppose, what would be called double salts, yet technically they are not exactly double salts. As to what becomes of this medicine, whether it is eliminated by the kidneys as bromine, or whether the arsenic is turned loose in the system, or the gold eliminated as chlorine, would be interesting. It is something like the question brought up by Dr. Howard some time since—the treatment of goitre by the use of iodine under the plan known as electro-phoresis—he alluded to a point which will perhaps help us out. The idea was that iodine being driven in by galvanic current, the iodide of potassium was decomposed and active iodine turned loose in the substance of the goitre. It is a well known fact that many beneficial results are obtained from elements in what we call the nascient state, and many chemical combinations may be affected in that way that would not obtain under different conditions. It is possible that the gold may carry a molecule of arsenic into the economy in this combination and give it up in such way as to cause the arsenic to be more effective than it would in any other way.

DR. T. H. STUCKY: My sole object in showing these cases and in bringing the subject before the Society was not to place myself on record that gold would cure these conditions, but it struck me as being a very peculiar coincidence that such marked results and such marked improvement should be manifested in so short a time. Out of a series of eleven cases of neurotic troubles in hospital and private practice, I have been surprised at the amount of improvement. One case is a very prominent man in a fashionable portion of the city, who has been living for a long time almost the life of a child, and who has been under the treatment of many neurologists. While visiting his wife, she heard of my having treated an other case and suggested the same remedy be given this gentleman. He had incontinence of urine, incontinence of feces, entire loss of control of the lower half of his body, lightening pains in the legs and over the region of the stomach, rest disturbed, and had been in about this condition for four years. I first gave him ten drops of mercuric bromide of gold and arsenic three times per day. He had to be lifted in and out of bed; his legs would become crossed in bed and his wife would have to uncross them at night; he would urinate involuntarily during the night; he was afraid to to go out in his carriage fearing he would have an involuntary evacuation of the bowels. He was given this treatment for two months without any apparent improvement, when I increased the dose one drop per day until I secured the effect of the arsenic; the dose was increased until he took twenty-five drops three times a day. He waked up one night complaning of a tingling sensation all over his body; I then ordered the medicine reduced to ten drops three times per day. His incontinence of urine has ceased; he has perfect control of the sphincter ani; he has considerable motion and strength in his legs, and can get up and down without assistance. There has been no further improvement, but certainly this has been a great advance over his previous condition.

There is another point about this solution that has struck me with force, that is its possible or probable usefulness in the treatment of glandular and joint troubles. It combines well with lime and salicylate of calcium. I have just had a case of enlargment of the cervical glands with calcareous change, which has been treated with bromide of gold and arsenic with a decided reduction in the size of the glands. His father gave a syphilitic history, and this patient had been treated for syphilis. I have also tried this remedy on other cases of glandular enlargments, and have been surprised at the rapid subsidence.

Another case, a prominent man who returned from Hot Springs some time ago, much emaciated, taking daily 450 grains of iodide of potassium; he also had unsteady gait and other nervous symptoms. The iodide of potassium was discontinued and bromide of gold and arsenic administered. While there has been no marked improvement in his gait, there has decided improvement in flesh.

Another case gave the history of pulmonary hemorrhage spitting of blood, yet there is no marked change to be found in the lung. She has been placed upon this agent, starting with four drops increasing one drop every day until she is in better condition and weighs more than she has in six years.

These cannot be coincidences, and the cases I have referred to demonstrate the usefulness of this agent in the treatment of syphilitic lesions. We have had several cases of syphilis in the clinic at the college that I did not refer to in my paper treated with this agent in all of which there has been a more rapid subsidence of all symptoms than usually obtains under the use of mercury alone. There has not been the marked ptyalism, nor the marked retraction of the gums, and the eruption has dried up very rapidly. The fact then that it enters into combination with lime, that it enters into combination with mercury in the form of a solution and is probably eliminated by the kidneys shows that it has a decided advantage over the old chloride of gold and sodium, which was not readily assimilated. Experience thus far has proven that this solution has a great advantage over iodide of potassium in that it does not produce gastric irritation. None of the cases in which it has been used have exhibited any gastric symptoms; it has produced no interference with digestion or the secretions, and it not only seems to have an especial action upon the constitution, but proves to be a

general tonic in its effect throughout the entire alimentary tract.

I have simply shown these cases with the hope that it might be of service in suggesting a new field of experiment. There is one more point upon which I would lay special stress. I made the error myself a year ago when the first specimen was sent to me by Dr. Barclay, of Pittsburg. We are inclined to discard its use too soon. We must push it like we do iodide of potassium for its full effect. I believe it is a good addition to our therapeutics and that its outcome is destined to be a great one. Certainly it cannot be explained that these three cases I have exhibited, and the others that have been treated, would have improved so markedly without its use. It has not been my experience that cases of locomotor ataxia suddenly turn in three or four weeks without treatment into a condition of decided improvement. It has not been my experience that within three or four days cases showing evidences of involvment of the lateral columns begin to assist themselves. It is not my experience that cases of paresis of a certain lot of muscles begin to take on action, and that patients state they can feel a tingling in that part, which I do not attempt to explain; nor do I attempt to localize its action exactly in these cases, I simply present the patients and give my experience in their treatment to emphasize my statement that I believe this remedy has a wide field of usefulness in the cure of neurotic conditions.

I have used bromide of gold and arsenic in two cases of incontinence of urione; in one of these there has been decided relief. I would like to call especial attention to its service in the treatment of choreic conditions; we get not only the benefit of the arsenic, but the sedative action of the bromide and alterative effect of the gold. I have used it with success in three cases of chorea without any other treatment.

CONTINUED DISCUSSION OF APPENDICITIS.

Dr. H. A. Cottell: When I proposed at the last meeting of this Society that the subject of appendicitis be again taken up at this meeting, it was not with the idea of entering seriously into the discussion myself. It is the old controversy of surgery vs. medicine. In these cases of so-called appendicitis, I suppose they are not limited strictly to the vermiform appendix; there is such a thing as typhilitis and perityhilitis as well as appendicitis, and it is not until the surgeons knife has brought to light the exact condition of things, that we are sure of our diagnosis. For instance if I should report a number of cases I believed to be appendicitis that got well without operation, the surgeons might say "how do you know it was appendicitis." In a certain proportion of cases I should have to confess I did not know whether it was or not.

In the course of practice extending over a period of twenty-two years, I can recall six cases of appendicitis, or inflammatory trouble involving the appendix or cæcum. In all those cases I had the benefit of able consultants, and in all except one I had the advice of one or more eminent surgeons. It has always been my rule when I made out the diagnosis of trouble in the appendicæl region to send for a surgeon that the patient might have the benefit of early operation if it was deemed advisable.

The first case was in the person of a child twelve years old; I had a physician in consultation; no surgeon saw the case. It was unquestionably one of intestinal obstruction from fecal accumulation in the cæcum; it could be easily made out. Under deep injection, the fecal accumulation finally worked loose and the patient made a good recovery.

Some time after that a little girl about the same age developed a decided tumor in the right iliac region with great tenderness; it was unquestionably cæcal and inflammatory. I called Dr. W. O. Roberts to see the case as soon as I was satisfied of the diagnosis, that the patient might have the benefit of early operation. He counseled against operative interference and the patient recovered.

The third case was one of somewhat obscure diagnosis; I would not contend that it was a case of inflammatory trouble in the region of the appendix, although the bowels were obstructed, and the symptoms seemed to indicate appendicitis. This case terminated spontaneously. Drs. Turner, Anderson and Roberts both saw the case in consultation, and both advised against operation.

The fourth case, in the person of a little boy about six years of age, was very remarkable to me in its outcome and history. There was great tenderness in the right

iliac region, with a tumor which was very marked. I saw the case in the evening, and as I expected to leave the next morning for Chicago, after visiting the patient with Dr. Roberts I left the case in his charge. There was no question as to the diagnosis, and we believed it was clearly a case calling for operation. Dr. Roberts decided to operate. The surroundings were such that an operation there even in the hands of this eminent surgeon was not to be thought of, and he tried to persuade the family to send the child to the Children's Hospital. I was absent for nearly four weeks; on my return I thought of the case and went as soon as possible, to inquire as to the outcome of the operation which I supposed had been performed. I was told that the family would neither send the child to the Hospital nor consent to an operation; but that the child had made a quick recovery.

The fifth case I saw in consultation with Dr. J. L. Howard. A clear diagnosis had been made; Dr. Roberts had also seen the case. The patient (a man) had grown suddenly worse in the night, and was in a state of collapse when I saw him. Dr. Roberts operated the next morning. It was with great difficulty that the appendix was found. It looked at one time as if the surgeon would have to give it up, but the appendix was finally reached and was found to be perforated. The patient had suppurative peritonitis at the time operation was performed, and the result was a fatal one, necessarily so I think on account the advanced condition of things and the weakness of the patient. Surgery did not have a fair test in that case. Up to that time all the cases of this trouble I had seen, none of which had been operated upon, had terminated in recovery.

The sixth case was one which was also seen in consultation with Drs. McMurtry, Larrabee and Ouchterlony. The patient was a child two years of age. It proved fatal. I am quite sure an operation would have been performed if the conditions would have permitted. Dr. McMurtry advised against the operation, giving as his reasons that the child was entirely to young to bear it. Besides its condition was a very extreme one. The expectant plan of treatment was therefore carried out, but with a fatal result.

Dr. A. H. Vance: Did you ever lose a case of acute peritonitis in the male?

Dr. H. A. Cottell: I do not recall a case that has died where a diagnosis of peritonitis was made. I remember one case which Dr. Anderson will also recall, occurring in a little boy. Diagnosis of appendicitis was never made, nor was diagnosis of peritonitis made. However, the child had symptoms which rather led us to believe that might have been the trouble; he died of heart failure. He never had a tumor, a dose of salts passed through his bowels the day before he died; he had no tenderness nor distension of the abdomen, and the truth of the matter is, I do not know what was the matter with him. We consulted as to the condition, but nothing definite was arrived at. It may have been a case of appendicitis.

Dr. J. A. Larrabee: Without any data, without statistics and without any record of cases, I simply wish to say that I have treated a great many cases of peritonitis before we attached the importance to appendicitis that we now do, and the entire ignorance of that cause, and while doing so and reflectsng upon this cause in our present enlightened and advanced state many of the cases might be claimed to have been connected with lesions of the appendix. Certainly it has been pretty thoroughly demonstrated at this time, but when I look over my practice I can recall many cases by memory alone of this character that have gotten well without operation. I can also recall cases that have died. I had one case very recently of peritonitis occurring in an infant three weeks old. I do not suppose that was connected with the appendix, but it was a typical case of peritonitis which recovered; it was syphilitic in its nature. I cannot report the cases by name and date, but I have lost cases of peritonitis in the male.

Just here I would call attention to a proposition I made at the last meeting, that each member of this Society hereafter report each case occurring in his practice of lesion in this region, whether it be appendicitis, peritonitis or otherwise, that a record may be made of it.

Dr. J. L. Howard: In the discussion of appendicitis at a recent meeting of this Society I believe the point was brought up that surgeons in England were not now operating very extensively for this condition. In the March 24th number of the *British Medical Journal* Mr. Jessop re-

ports four cases of appendicitis of the type that Dr. Cartledge laid so much stress upoh, *i. e.* stenosis by a fibrous band near the proximal end, the distal portion being very much distended with mucous, but without perforation.

Dr. Grant operated on a case of appendicitis last week at the clinic, in which the symptoms were very marked and the diagnosis unquestionable. When an incision was made an abscess was found filled with pus, walled off from the peritoneal cavity and entirely mural. No adhesions were broken down as it was not deemed wise to invade the cavity which was not involved, but the surgeon stated that he believed the appendix was the *fons et arigo mali* and that the appendix would be discharged with the pus.

Of course in a case of this kind no one can deny that opening of the abscess was the proper procedure.

Dr. Turner Anderson: In regard to peritonitis in the male, I want to say that I have a very distinct recollection of two cases I have had where the death certificates have been signed, in all probability by myself, the cause of death being given as peritonitis, However, both these were clearly cases of traumatic peritonitis. One was a little boy that had been punched in the abdomen by a playmate, in being forced into line marching from school. He died five or six days later from peritonitis. Another occurred in a boy fifteen years of age, who also gave the history of having been struck in the abdomen by some means.

I stated at the last meeting what I have said on many occasions, that I did not regard perityphlitis of very much consequence until after the nomenclature had been changed; until it was denominated appendicitis, I had very little concern in regard to the disease. I stated as a personal experience extending over more than a quarter of a century that I had not seen a case which had terminated in death. I simply gave this as a personal experience; I do not doubt what other men say; I do not question the veracity of other reports, nor do I question the fact that there are cases which should be operated upon. I remember very well the case Dr. Cottell refers to; there was a large tumor in the classical region, and it looked very much like a case which ought to be operated upon, and that very promptly; Dr. Roberts also saw the case, and I told him perhaps it was a case demanding operation and I would sanction it if he desired to operate. The mother declined to have the operation performed. I also made the statement at that time that I had seen many cases of a similar character which had gone on steadily progressing in a satisfactory way and finally recovered, and I believed that this boy would also get well without operation, and he did get well. It was only a short time before this that Dr. Roberts had seen another case with me where there was a large tumor, and where it looked as though suppuration and rupture might occur. Operation was proposed and refused. The case went on under ordinary medical treatment and made a satisfactory recovery.

Dr. A. M. Vance: I would like to exhibit an appendix taken from a man twenty-three years of age, after having suffered with appendicitis four days. The patient was in a condition of active sepsis; there was quite an accumulation of very offensive pus, and this necrotic appendix was found. I first saw the patient at three o'clock to-day and operated ten minutes afterwards. Sepsis was evidently established from this collection of pus, and while the probabilities are the patient will die from sepsis, I believe the cavity is shut off.

The question has been mentioned that not many operations were being done at present time for appendicitis in Great Britian: I have here a quotation from a recent issue of the *British Med. Journal*, the conclusions of G. H. Sanborn in regard to operative measures in appendicitis are:

1. That in all cases the physician is concerned only in the early recognition of the disease, the subsequent treatment to be left to the surgeon.

"2. That the catarrhal or mild form of appendicitis may be considered the only medical form of the disease; and delay in operating may be encouraged to a reasonable extent.

"3. All cases of appendicitis which, at the end of thirty-six hours from the beginning of the attack, show signs of increasing disease, should be operated upon.

"4. That the majority of so-called recoveries, treated medically are not recoveries in the full sense of the word, but simply a respite which enables one to

settle worldly affairs, and take out a life insurance policy, in anticipation of a fatal termination.

"5. The early surgical treatment of appendicitis enable us to avoid in every case uncertain results of a spontaneous cure, the danger of recurrent attacks, and the often fatal general peritonitis in apparently mild cases,—*Brit. Med.*

I would like to make a point in regard to the conservative treatment of appendicitis: The question has been asked as to how many members of this Society for anstance have treated cases of acute peritonitis in the young male; in most cases the question has been answered in the affirmative. Since the meeting at Dr. McDermott's one month ago, Dr. Cartledge and myself have taken occasion to look over the death certificates of the city of Louisville for the last twenty-three years and find 168 cases of acute peritonitis in the male, the age averaging twenty-eight years, and nearly every prominent physician in the city has his name affixed to one or more of these death certificates. We believe that at least seventy-five per cent of cases of acute peritonitis in the young male ean be attributed to the appendiceal region, as there are few other causes outside of traumatism that will cause peritonitis in this class of cases. We excluded in these statistics all cases at all doubtful; all cases of intussusception; all cases of obstruction of the bowels; all cases of volvulus; all cases where traumatizm was a factor, and it may be assumed too, I think, that a great many of the so-called obstruction of the bowels, volvulus, intussusception, etc. are caused by paresis due to inflammatory troubles in the right iliac fossa more than likely having their origin in the appendix.

Dr. L. S. McMurtry: (Visiting) There is very little I can say, as the subject has been so thoroughly discussed by the previous speakers. I am somewhat surprised that there should be any question about the gravity of the disease, or importance of surgical treatment. There can be no question about its being a very murderous disease, and I am surprised that my friend Dr. Cottell, considering the disclosures which have been made in regard to appendicitis within the last few years, still separates it into typhlitis, perityphlitis, etc. It has been demonstrated beyond question that practically all inflammatory conditions in the right iliac fossa are of appendicular origin. I believe that we can never settle any question in medicine or surgery by the recital of cases of doubtful diagnosis. We find fecal accumulations in the cæcum, non-inflammatory in character; we may have cases of catarrhal appendicitis, a large proportion of which go on to recovery; recurrence is common and ulceration and perforation may take place—in other words the case assumes a different phase of the disease and may result fatally without operation. The number of deaths from appendicitis is simply enormous at the present time. The Health Officer's Report for the City of Louisville at the end of every week will show five to six deaths from peritonitis; it is reasonable to suppose 2½ per cent. of these in males, and 1½ per cent. in females, are due to appendicitis. These facts in regard to the disease are recognized generally, and it seems to me after inspection of an appendix such as shown to-night, all question of the fatal and serious character of the disease would be placed forever at rest. To my mind the treatment of these cases is nothing but the application of a general surgical principle that is recognized in all other parts of the body; that is, when there is an abscess anywhere, to open and evacuate it.

Another feature about the surgical treatment of the disease is that we may have a large number of cases of appendicitis which apparently get well, and pass out of observation, and the disease will recur and ultimately require operation, in a large proportion of cases. In England, as has been mentioned by Dr. Vance, appendicitis is now universally regarded as a surgical disease, and all over this country professional opinion is very rapidly changing from the medical to the surgical side. There is one thing by which we are apt to be misled, that is the conclusions to be derived from very late operations; where the disease has gone on until septic peritonitis has spread; where there is a large accumulation of pus with a necrotic appendix and the patient has become thoroughly septic; there is nothing to be expected in such cases from any operation. Eleventh-hour operations are nearly all disastrous and are not a fair test of the operative treatment of any disease. The operative treatment of appendicitis is eminently satisfactory

when done early. In some cases very little surgery is required; in such as the one referred to by Dr. Larrabee it is only necessary to open the abscess, evacuate the pus, irrigate it and put in a drain. In many cases it is not advisable to carry out ideal surgery. However, I believe in every case where the patient's condition will permit, the appendix should be removed when it is the source of the tronble, just as we would remove a sequestrum of bone causing abscess in any other part of the body. There has been the greatest advance in the treatment of this disease. I believe it will not be a year until the subject can be discussed, and there will be no difference of opinion.

Dr. T. L. McDermott: I do not indorse what Dr. McMurtry has said, of course if I could, I would not have written the paper read before this Society some time since. To my mind the question of diagnosis of appendicitis remains the most important factor, and, until we arrive at a more satisfactory classification, we can never clear up the proper history of these cases. We should take the cases in which surgeons have been called early, operation advised and refused; then take the cases treated medically, and by comparing results with those in which operations have been performed, we may be able to reach a satisfactory conclusion. Cases are frequently reported where diagnosis had been made of appendicitis, and operation revealed a normal condition of the appendix, the trouble having been due to some lesion of the liver, kidney or other organs; the question then comes up, how can we arrive at an accurate diagnosis?

My own opinion is that the safest plan is to follow the conservative line of treatment in these cases until such time as some light is thrown upon the matter, as certainly the history of appendicitis is still a mystery, and we are largely at sea as to the diagnosis.

TREATMENT OF PERIPHERAL NEURITIS.

Leyden (*Berl. klin. Woch.*, No 20, 1894) discusses the treatment of multiple neuritis. He considers that in the case of neuritis following acute specific diseases, care during convalescence as to nourishment, rest in bed, and avoidance of overexertion contribute to prevent its occurrence. "Etiological treatment" (removal of the cause) in neuritis due to alcohol or lead, and treatment of the primary malady as in diabetes is of the first importance. There is no specific remedy for multiple neuritis and treatment by drugs does not play a very important part. Owing to the fact that rheumatism is not infrequently an element in the etiology, salicylate of sodium and other anti-rhenmatic drugs had been used without producing any good results in the majority of cases. Iodide of potassium was of use only now and then, and mercury was of doubtful value. Antipyrin, phenacetin, exalgin, euphorbia, and methylene blue were sometimes of use for the relief of pain, but it was often necessary to resort to morphine, chloral, sulphonal etc. Strychnine, formerely much used, but lately fallen into the background, deserved to be tried; by increasing the excitability of the affected muscles, it favored the return to normal function and nutrition; it ought especially to be resorted to in progressive cases in which the respiratory movements were threatened. Leyden prefers to use it as a subcutaneous injection, gr. $\frac{1}{75}$ to gr. $\frac{1}{50}$ twice daily. Massage and baths were valuable auxiliaries which were indicated, especially the latter, in the later stages of the disease. General hygienic treatment was of much importance. Rest—as a rule rest in bed—was of the first importance in the early stage; in the later stage, feeding. Finally, in the latest stages of all, moral suasion, rousing the patient's latent energies, was often of great value. Passive movements, and encouraging the patient to make active movements, were generally attended with better results than massage in this stage. Electricity, formerly used too much, was now used too little, but its usefulness was greatly limited by the fact that in many cases the pain caused was too great to permit the treatment to be continued.—*British Med. Jour.*

CURRENT LITERATURE REVIEWED.

IN CHARGE OF ELLISTON J. MORRIS, M. D., AND SAMUEL M. WILSON, M. D.

THE AMERICAN JOURNAL OF OBSTETRICS.

for August contains a paper by Dr. Thomas A. Ashby on

The Influence of Minor Forms of Ovarian and Tubal Disease in the Causation of Sterility.

As the result of his observations, the author draws the following conclusions:

First. The adjustment of the tube and ovary during ovulation is effected in the human female by the most delicate mechanical arrangement and may be defeated by trivial mechanical interferences.

Second. In animals that habitually have multiple pregnancies a more perfect mechanical provision is made for the reception of the ovum by the tube. The number of ova impregnated seem to bear a close relation to the perfection of the arrangement which is provided for their passage into the tube. Thus, in the bird will be found the most perfect type of mechanical adjustment, in the women the most intricate and difficult.

Third. The adjustment of the pavilion of the ovary may seem to be set aside by the most trivial vices of structure and disease, resulting in relative or absolute sterility.

Fourth. Sterility is due to minor diseases of tubes and ovaries to a greater extent than has been recognized. In an investigation of the etiology of this condition this fact should be considered in connection with an investigation of other causative influences.

Fifth. The highest aim of surgery is to restore and not to destroy function. In the treatment of minor forms of ovarian and tubal disease this fact should be borne in mind. Organs should not be sacrificed to the rule of expediency, but should be preserved in deference to a law of genuine conservatism.

J. C. Webster, B. A., M. D., F. R. C. P. E., contributes an article on

The Classification of Ectopic Gestation.

presenting the following table. Cornual pregnancy is not included in the table.

I. AMPULLAR, in which the gestation begins in the ampulla of the tube. This is by far the most common origin.

1. *Persistent.* In rare instances the tubal gestation may go on to full time.

2. *Rupture may take place early into the broad ligament*—supperitoneo-pelvic, tubo-ligamentous, extraperitoneal, broad-ligament gestation.

(a). The gestation may continue to develop —subperitoneo-abdominal.

(b). A secondary rupture of the subperitoneo-pelvic gestation may take place into the peritoneal cavity.

(c). The gestation may come to an end:

(a). By the formation of a hematoma

(b). By suppuration.

(c). By mummification, adipocere, or lithopedion formation.

3. *Rupture may take place into the peritoneal cavity.*

(a). Tubo-peritoneal gestation, in which the escape of the fetus in membranes occurs into peritoneal cavity, the placenta remaining in the tube, its development continuing.

(b). The gestation terminates in various ways: By the formation of a hematocele, the patient dying from the shock and loss of blood, or from peritonitis. In some cases absorption of the mass may occur. In others mummification, adipocere, or lithopedion formation may take place in the festus. Suppuration may result.

4. *The gestation may be destroyed:*

(a). By the formation of a tubal abortion and its passage through the fimbriated end of the tube into the peritoneal cavity.

(b). By the formation of a hematosalpinx.

(c). By the formation of a mole.

(d). By suppuration resulting in a pyosalpinx.

(e). By absorption after early death, by mummification, adipocere, or lithopedion formation.

II. INTERSTITIAL—The gestation may develop in the interstitial portion of the tube:

1. The gestation may go on to full time.

2. Rupture of the gestation into the peritoneal cavity may occur.

3. Rupture into the uterine cavity may occur.

4. Rupture both into the uterine and peritoneal cavities may occur.

5. Rupture may occur between the layers of the broad ligament.

6. After the death of the fetus it may remain in its sac, and possibly may undergo the same changes as in other forms—*e. g.*, Mummification, adipocere, or lithopedion.

III. INFUNDIBULAR—The gestation begins in the outer end of the tube or in an accessory tube ending. Under this heading are to be included the forms described as tubo-ovarian and tubo-abdominal, names which appear to the author to be unnecessary, since the gestation is a tubal one in origin, the end of the gestation sac merely becoming adherent to the abdominal wall, the ovary, or other of the viscera.

In an article on

Surgical Intervention in Tubercular Peritonitis,

Dr. O. S. Runnels says "It is still too early, the years are yet too few, in which to close the discussion or fix the verdict upon many of the claims for this procedure. But this is established beyond cavil: tubercular peritonitis is essentially a surgical disease and cannot be successfully managed without surgical intervention. It is settled that tubercular peritonitis, verified as such by microscopical proof, is curable by celiotomy, and that this remedy is of primary importance in the treatment of such cases. It is proven that the bacillus culture can be arrested if it has not

gone too far, and that the bacillus itself is a *post-hoc*, a follower, rather than a *propter-hoc*, and originator. In the light of present knowledge long-continued mystery concerning abdominal maladies is inexcusable. The exploratory incision is the indicated remedy in every such condition, and will enable the adviser to avail himself of the knowledge requisite for wisest procedure.

Dr. Eugene R. Corson in a paper entitled

A Suggestion in the Operation for Vesico-vaginal Fistula,

reports a case in which he undertook to close the opening after the flap splitting method advocated by Mr. Tait. Two attempts were failures and the author advises the young operator to stick to the old way. At the third attempt the author practiced the following device for drawing the parts within reach of the knife. He cut in half a small hollow rubber ball, such as is found in the toy shops, pierced the centre of this rubber disc with the small blade of a penknife, and passed through the slit made the shank of an ordinary shoe button, the shank appearing on the convex side of the disc. Through this was passed a strong silk ligature, strong enough to bear considerable traction. He then pared the disc down to a size permitting its passage through the fistula and giving him sufficient margin for traction. Curling it up, it was passed, with the aid of dressing forceps, into the bladder, where it expanded, enabling him on traction to draw the vaginal wall well down and within easy reach of any operative measure Through the counter pressure of the disc the paring of the edges of the fistula was greatly facilitated, especially in checking hemorhage. When all the sutures are placed they can be drawn aside and the disc drawn through the pared fistula. When the fistula is too small, and the operator is afraid of injuring the pared edges, the disc can be cut up by scissors and removed peicemeal by the dressing forceps. The author mentions the following points in the use of this device—Choose a rubber ball moderately thin, say the twelfth of an inch, so that the rubber disc may be readily curled up and passed into the bladder with the dressing forceps. Before curling it up draw the button well out an inch or more, that the button head be not in the way. On traction being made the shank immediately slips back into the slit made by the penknife. Make the sutures sufficiently long to permit of their being well drawn out into loops preparatory to removing the disc from the bladder.

Dr. Thomas C. Smith reports

Cases of Excessive Secretion of Milk,

in one of which the daily secretion amounted to half a gallon daily in addition to that required by the child. In the second instance the waste milk amounted to three pints. In regard to the treatment of such cases the author states that as the appearance of the menses causes a diminution in the supply of milk the advice had been given to bring on the menses. Uterine irritation is also recommended. Hot vaginal douches have also been employed, though strapping and bandaging the breasts seem to do more good than any other treatment. In the author's expealence, ergot has failed completely. The combination of opium and antipyrin seemed to have the desired effect in the author's first case, but was not resorted to till the affection had lasted nearly three months and while the author would use it in any future case he does not hazzard the asumption that it wrought a cure in the case reported.

Dr. G. Wythe Cook contributes an article on

The Treatment of Abortion.

The patient should be kept at absolute rest and such drugs employed as will conduce to nervous sedation and weaken muscular action until such time as the abortion becomes inevitable. When the abortion cannot be prevented the author is of the opinion that the uterus should be evacuated as speedily as possible. If there is any considerable hemorrhage the tampon should be used. This, according to the author, serves the double purpose of controlling the hemorrhage, and such blood as may escape is retained within the uterus and may dissect off the fetal appendages, in that way facilitating the emptying of the uterus. The best way to apply the tampon is to insert some iodoform gause into the cervical canal and then pack the vagina with long strips of aseptic gause.

If the entire ovum does not come away, the author unhesitatingly advocates the radical method of dealing with it by removal by manual means. He does so for these reasons: "So long as any portion of the membranes or placenta remains within the uterus, just so long is the woman menaced by the danger of hemorrhage or septicemia, or both; and there is no justification in allowing these foreign bodies to remain shut up within the uterine cavity because it has sometimes been done without any disasterous results. Hemorrhage may occur at any moment, or septicemia, by its insidious developments, may sap the strength and destroy the life or produce a condition of chronic invalidism that makes life a burden. Again an enlarged uterus containing a foreign body remains decidedly hypertrophied, and when finally evacuated its walls may remain permanently thickened and its cavity enlarged, these conditions favoring dislocations." The author adopts the plan of emptying the uterus with the fingers if possible, otherwise he sees no objection to the use of the curette. If the cervical canal has closed, a laminaria tent or other cervical dilator should be introduced. He states that more difficulty will be experienced in removing the secundines in an abortion procured by instrumental means than in a spontaneous miscarriage, because in the former case the tissues are more healthy and the placenta and membranes are more adherent. If the uterus has been thoroughly evacuated there will be little else to do, as the lochial discharge will be slight and uterine involution rapid.

The author also enters a little into the question of the duty of the physician to the State in abortion. While believing that it is the

duty of the physician to preserve inviolate any facts that he may have learned in his capacity as physician yet abortion is such a a crying evil that the author is in doubt as to the proper course to persue and evidently leans to the side of shielding the woman. When the patient dies as the result of a criminal abortion the author is of the opinion that the death certificate returned by the attendant should state the true cause of death. In case of the woman surviving he is not so sure of the course the attendant should take, on account of the apparant legal difficulties in legally establishing the facts.

PERISCOPE.

IN CHARGE OF WM. E. PARKE, A.M., M. D.

MEDICINE.

Etiology of Craves's Disease.

Grube (*Neurol. Centralbl.*) maintains the infectious nature of Graves's disease. He narrates a rapidly fatal case in a woman, aged 50. Three of her four children had died; one of convulsions, two of "nervous fever." As a girl she was said to have been anæmic. Some years ago she began to suffer from nervous abdominal pains, and during the last half year she had had occasional asthmatic attacks, especially in the night. The patient herself attributed her illness to the shock caused by hearing that there was sugar in her urine (said to be about 9 per cent.) six weeks before her death. The asthmatic attacks became worse and a swelling appeared in her neck. The skin of her face appeared somewhat bronzed, as if by the sun. Exophthalmos was not much marked, but the signs of Stellwag and Grafe were both present. The thyroid gland showed hypertrophy of the left lobe and isthmus. Many enlarged lymphatic glands could be felt in the neck. The heart was much dilated, but the heart sounds clear; the pulse was full, strong, and frequent (120 to 130). There was considerable dyspnœa, especially at night, so that the patient could not lie down in bed; some rhonchus. A certain amount of œdema in the legs. Urine (specific gravity 1030) showed trace of albumen and sugar two weeks after the supposed commencement of the disease. Some tremor in the upper extremities. Slight fever in the evenings. She died in about six weeks from the supposed commencement. Granting the infectious nature of the disease, the infective agent may act (1) on the thyroid gland, causing perversion of its function, which Mobius has suggested as the cause of Graves's disease, the nervous system being affected secondarily; or (2) on the thyroid gland and the nervous system; or (3), and more probably, the infective agent or its products might act on the nervous system directly. Against the nervous theory of Graves's disease it has been urged that the symptoms do not point to one part only of the nervous system being affected; this is, however, no argument against the infectious theory, for several different parts of the nervous system could be affected by a toxin, though the medulla oblongata might be especially susceptible or its rich network of blood vessels might facilitate the working of the infectious agent. The causes which are commonly invoked as starting points for Graves's disease—shock, excitement, overexertion, etc.—can hardly be considered as of first moment, except in so far that they may weaken the body generally and render it less able to resist infection. Grube adds that he can further adduce as arguments in favor of the infectious theory of Graves's disease: (1) That the disease may supervene in cases of endemic or hereditary goitre; (2) the occurrence of swelling in lymph glands, noticed by Muller and in this case; and (3) that a hereditary character of Graves's disease has been recognized.

The Value of Sugar and the effect of Smoking on Muscular Work.

As the result of a series of experimental researches in the Physiological Institute, Turin, as to the value of sugar and the effect of smoking on muscular work, Vaughan Harley (*Journ. of Phys.*,) has come to the following conclusions: (1) The periods of digestion as well as the kinds of food taken have a marked influence on voluntary muscular energy. (2) Irrespective of the influence of food, there is a periodical diurnal rise and fall in the power of performing muscular work. (3) More work can be done after than before midday. (4) The minimum amount of muscular power is in the morning about 9 A. M., the maximum about 3 in the afternoon. (5) Regular muscular exercise not only increases the size and power of the muscles, but has the effect of markedly delaying the approach of fatigue. (5) The amount of work performed on a diet of sugar alone is almost equal to that obtained

on a full diet, fatigue, however, setting in sooner. (7) In fastening, large quantities of sugar (500 g.) can increase the power of doing muscular work during 30 voluntary contractions from 26 to 33 per cent, while the total gain in a day's work may be 61 to 76 per cent., the time before fatigue sets in being also lengthened. (8) The effect of sugar is so great that, when added to a small meal, it can increase the muscular power during 30 voluntary contractions from 9 to 12 per cent., while the total increase in work may be from 6 to 39 per cent., the approach of fatigue being at the same time retarded. (9) When added to a large mixed meal, sugar can increase the muscular power of 30 contractions 2 to 7 per cent., the increase in total work being 8 to 16 per cent, and a marked increase in the resistance to fatigue is shown. (10) Two hundred and fifty grammes of sugar taken in addition to a full diet increases the day's work; the work accomplished during 30 voluntary muscular contractions shows a gain of from 6 to 28 per cent., the total day's work giving an increase of power 9 to 36 per cent., and the time before fatigue sets in being lengthened. (11) Moderate smoking, although it may have a slight influence in diminishing the power of doing voluntary muscular work, neither stops the morning rise nor, when done early in the evening, hinders the evening fall. (12) Sugar taken early in the evening is capable of obliterating the diurnal fall in muscular power that occurs at this time, and increases the resistance to fatigue.

Gonorrhœal Stomatitis and Ophthalmia in Newborn Child.

Leyden, of Breslau (*Centralbl. f. Gynak.*,) writes that a single girl, aged 20, was recently delivered, a little before term, of her first child. There had been moderate vaginal discharge during the last months of pregnancy; on that account the vaginia was freely washed out with lysol during the entire puerperium, so that the discharge steadily disappeared. The labour was normal. The child (a girl) was rather weakly. Directly the head was delivered the eyes were washed with a 1 in 7,000 solution of sublimate. Until the evening of the sixth day the child seemed fairly well; it took the breast, the motions were normal, and the eyelids did not stick together; but the skin became jaundiced, and on the morning of the seventh day there were all the signs of gonorrhœal ophthalmia in the right eye. A large pustule was found on the mucous membrane of the upper lip, close to the gum. The pus which it contained was found full of gonococci. Notwithstanding all precautions (the case was in the Breslau Lying-in Hospital) the left eye was attacked on the next day. The purulent inflammation of the mouth increased, and there was diarrhœa. The eyes, however, were saved, and after frequent washing of the buccal mucous membrane with the 1 in 7,000 sublimate lotion, the purulent crusts which had formed disappeared, and nine days after the first appearance of the pustule a desquamating area marked the seat of disease. The mother's nipples did not become sore; the child, however, was fed with the bottle directly the soreness of the lip was detected.

Intravenous Injections of Corrosive Sublimate.

At the meeting of the Eleventh International Medical Congress, in Rome, Guido Bacelli (*Berliner Klin. Wochenschrift*, said that intravenous injections had been suggested by him and employed for the cure of malaria. Professor Nothnagel maintains that they are unnecessary, as subcutaneous injections can accomplish just as much without disagreeable consequences. But Bacelli's results, published in 1890, were brilliantly successful as regards the treatment of severe forms of malaria with intravenous injections of neutral salts of quinine, and they contradict Nothnagel's opinion. Since then Bacelli has experimented with corrosive sublimate given by intravenous injections for syphilis. Experiments upon animals were tried first. He then tried the new method in two cases of cerebral syphilis which had resisted cure by other methods, including inunction and hypodermic injections of mercury and iodide of potassium in large doses. The results were excellent. Other cases followed, so that now the method is employed by many Italian physicians. The solution Bacelli employs is as follows:

℞

Hydrarg. bichlor.	1 part
Sodii chlor	3 parts
Aq. dest	1000 parts

The skin is cleansed and rendered aseptic, and a syringeful of the solution is injected into a vein at the elbow, back of the hand, or thigh. The veins are first made prominent by constriction. The injection must be into the lumen of the vein, otherwise pain and swelling will result. In a few minutes (five to six) mercury is excreted in the saliva. The "cure" begins with the injection of 1 milligramme of corrosive sublimate daily,—that is to say, 1 cubic centimetre of the solution (1 to 1000; then the quantity increases from 2 to 8 milligrammes (the maximum dose). For four milligrammes a two-per-cent. sublimate solution may be employed, so as to avoid the injection of too large a quantity of fluid. In exceptional cases he begins the treatment with doses of 4 to 5 milligrammes.

Bacelli calls special attention to the following points: 1. The small quantity required. 2. The possibility of overcoming many symptoms quickly,—symptoms which indicate direct blood-poisoning with the syphilitic virus. 3. The benefit and widely-distributed action upon vessel walls which are the specially-favored seat of syphilitic alterations.

Bacelli also employs sublimate injections for the cure of echinococcus cysts. The cyst is punctured and about thirty cubic centimetres of the fluid withdrawn through a trocar; 20 cubic centimetres of one-per-mille sublimate solution are then injected, the trocar withdrawn, and a dressing applied. In five days the patient is dismissed cured. The parasite is killed, and the subjective and objective symptoms subside by degrees.—*Therapeutic Gazette.*

Treatment of Typhoid Fever by Carbolic Acid and Chloroform.

The author has, in treating typhoid fever, resorted to the simultaneous use of carbolic acid and chloroform, each of which, employed by itself, has already yielded good results in dothinenteritis. He employs the following formula:

Carbolic Aid (pure)	2.4	gme. (37 grn.).
Spirit Chloroform	.8	" (2½ fl. drs.).
Tincture Cardamom	12	" (3 ")
Syrup	60	" (1⅛ fl. oz.).
Saturated Chloroform-water	275	" (9 ").

Two tablespoonfuls in a little ice-water every two hours.

The patient takes, on the first day, two tablespoonfuls of this potion five times in the course of the twenty-four hours; he repeats the same dose seven times on the next day, and ten times from the third day on, until a marked fall of temperature with a corresponding improvement of the general condition has set in. This result having once been obtained, the daily dose is gradually diminished to six tablespoonfuls and continued for at least a week after the temperature has become normal.

This mode of treatment is said to shorten the duration of the affection, to remove complications, and to rapidly suppress intestinal tympanites, diarrhœa, fœtor of the stools, delirium, and coma; also to promote the assimilation of food and to hasten convalescence.

Carbolic acid, as administered in the above mentioned doses, is said to have always been well tolerated; and the urine hardly ever became darker, and never assumed a blackish color.—*American Medical Surg. Magazine.*

Turpentine in Carcinoma.

John Clay.—(*Medical Press und Circular and New Albany Medical Herald.*)—The author reports five cures of grave carcinoma by means of Chian turpentine. Such favorable results cannot be obtained when the disease has progressed so far as to invade the general system; but even then an improvement can be effected so far as concerns pain and hemorrhage, so that turpentine must be regarded as a palliative agent of the greatest value in carcinoma. Besides the five cases mentioned above the author has treated, during the last nine years, a number of patients with uterine carcinoma with Chian turpentine, who are still alive and present every appearance of health. When it becomes necessary to operate for carcinoma of the mammæ, it is a good plan, according to the author, to administer turpentine for three weeks before the operation, in order to destroy the germs, which constitute the cancerous infiltration of the surrounding tissues, and after the operation the medicine should be kept up for a year, in order to prevent a return. The author has used this method for the last six years in many cases, and has never seen a return. In the treatment of carcinoma, opium and morphine should be almost entirely dispensed with, since their prolonged use in increasing doses contributes materially to produce the cachexia and anemia. On the other hand, Chian turpentine in connection with antipyrine acts as a palliative and has no bad after-effect.

As regards the mode of administration, the author prefers the pills to the mixture, but they are not to be used in cases of cancer of the stomach or rectum, as they are not digested. The pills are to be mashed or broken up and taken in milk, to the number of nine to twelve in twenty-four hours. In conclusion, the author warns patients and physicians that patience is necessary in carrying out this treatment, since three weeks and longer may pass before any sign of improvement is visible.—*N. Y. Therapeutic Review.*

Laudanum in the Treatment of Diphtheria.

It is well known that, in children affected with diphtheria, the dyspnœa and inspiratory spasms visibly increase under the influence of fright and restlessness, whilst they diminish when the little sufferer quiets down. This fact suggested to Dr. C. Stern, of Dusseldorf, (*Medical Week*) the idea of administering opium in the form of laudanum, to children affected with diphtheria, in the hope of thus exerting a favorable influence on the respiratory disturbances due to the laryngeal stenosis. The results obtained by this treatment seem to be worthy of note, inasmuch as Mr. Stern was frequently enabled by this means to avoid tracheotomy in cases in which this appeared before administration of the laudanum to be the only resource.

He gives the little patients, according to their age and the intensity of the respiratory difficulties, from two to five drops of vinum opii, repeating this dose several times when necessary. In the case of children over a year old, he generally begins by administering three drops of laudanum in a teaspoonful of sweetened water. If the effect of this dose is not sufficiently marked, he gives in half an hour two drops more of laudanum. This second dose is said to frequently determine a notable diminution in the cyanosis and drawn conditions of the features. As soon as the respiratory disturbances appear again to be on the increase, another dose of the remedy is given. In this manner, laudanum may be administered for several days in succession at the rate of from three to five drops daily, with careful watching of the child both with reference to the narcotic effects of the drug and the possible need of tracheotomy, although the laudanum treatment in the majority of cases permits of dispensing with this operation.

This treatment is said to be particularly efficacious, when instituted early, especially from the very onset of the respiratory disturbances. Lastly, in cases in which tracheotomy eventually becomes unavoidable, the laudanum treatment makes it at least possible to delay the intervention without inconvenience, which is of considerable importance when the patient has to be transported to a hospital to undergo the operation.—*N. A. Practitioner.*

SURGERY.

Gunshot Wounds of the Intestine.

DEDUCTIONS.

1. Laparotomy is the only rational procedure in all cases of gunshot wounds of the abdomen where there is reasonable evidence that the ball has entered the abdominal cavity, and each moment's delay will materially lessen the chances of recovery.

2. If there is a reasonable doubt as to whether or not the ball has entered the abdominal cavity, give the patient the benefit of that doubt by doing an early exploratory operation for diagnostic purposes.

3. In wounds of the pancreas complicating gunshot injuries of the intestine, a resection of this gland may be done, care being taken not to include the head or common duct, as death invariably follows such procedure.

4. The segmented catgut rubber ring being uneffected by the imbibition of intestinal secretion, is one of the very best aids in circular enterrhaphy or lateral anastomosis.

5. A ring composed wholly of catgut is entirely worthless as an intra-intestinal support on account of its highly absorbable qualities.

6. When the Lembert stitch includes only the serous, or a part of the muscular coat they do not as a rule, ulcerate their way into the bowel as is claimed by some, but usually become encysted, and remain near their place of introduction.

7. An intestinal wound when properly treated usually becomes securely sealed in from six to twelve hours by the formation of plastic peritoneal exudation; but this must not be too confidently relied upon as it may be very materially retarded.

8. If there arises evidences of a supurative peritonitis, do a second abdominal resection, disinfect the cavity and apply drainage. M. L. Hefeelfinger, M. D., in *Texas Curier-Record.*

—o—

Aromatic sulphuric acid was Sydenham's favorite remedy in bleeding at the nose or in spitting blood. Ten to twenty drops three or four times a day.

The Occurrence of Hemorrhage After Operation for the Removal of Adenoid Tissue from the Naso-Pharyngeal Vault; with the Report of a Fatal Case.

The case reported by Dr. J. E. Newcomb (*American Journal of the Medical Sciences*), is that of an anæmic, somewhat strumous boy, nearly four years of age. There was no evidence of hæmatophilia. The operation was done with the usual precautions. Gradle's forceps and Gottstein's curette were employed. Soon after the child got home an oozing hemorrhage began. The *physician*, however, was not *sent for* until *twelve hours later*, when the child was found in a desperate condition from loss of blood. *Death followed shortly.* Of eleven cases of hemorrhage (reported by Rousseau, four) occurred in the first decade of life, five in the second. The youngest age recorded is four years (Delavau), the oldest is twenty-eight (Ruault.) The time after the operation when bleeding began varied from immediately to twenty hours. Tamponning was the favorite measure of relief employed. Patients from whom adenoid tissue if removed ought to be kept under careful observation for at least twenty-four hours.—*International Medical Magazine.*

Abscess.

Never try fluctuation across a limb, always along it. Never forget that: (1) Abscesses near a large joint often communicate with the joint. (2) Abscesses near a large artery sometimes communicate with the artery. (3) Abdominal wall abscesses sometimes communicate with the gut or the solid viscera.

Never forget that early openings are imperative in abscesses situated: (1) In the neighborhood of joints. (2) In the abdominal wall. (3) In the neck, under the deep fascia. (4) In the palm of the hand. (5) Beneath periosteum. (6) About the rectum, prostate and urethra.

To wait for abscesses to "point" or to "burst" in these situations is culpable as well as cowardly.

Remember the frequency with which hematomata and traumatic aneurism have been mistaken for abscesses, and incised with untoward results.

Do not open an abscess anywhere near a large artery without first using a stethoscope, and then only by Hilton's method (*i. e.*, scalpel, dressing forceps).

Never, under any circumstances, use for exploratory puncture "that surgical abomination—a grooved needle"—for it will allow contamination of all the tissues through which it brings the fluids. (Thornton.)

Never plunge in opening abscesses; never squeeze the sac after doing so.

Do not forget that your incision should radiate: (1) In abscesses pointing near the nipple. (2) In abscesses near the anus. (3) In scarifying the chemosis of the cornea.

And that your incision should be longitudinal: (1) In the hand. (2) In the urethra. (3)On the vertex.

Do not forget that incisions for abscesses in neck and face should run parallel with the wrinkles and folds.

Do not be afraid of hurting the lacteal tubes in mammary abscess. More harm is done to the gland by the enlargement of the walls of the abscess than by a free incision.

Never make a palmar incision except in the middle of the lower third and in the axial line of the fingers or at the sides of the palm.

Do not forget, in opening a deep abscess in the lumbar region without the projection of the abscess, to cut down opposite a transverse process, not between them, for fear of wounding a lumbar artery.—*Atlanta Med. and Surg. Journal.*

GYNECOLOGY.

The Early Treatment of Carcinoma Uteri.

The large number of hopeless cancer cases applying to me for relief have induced me for the past three years to adopt certain stringent rules with regard to my own patients, which I have taught for the same period in my lectures at the Johns Hopkins Hospital.

The end in view is two fold—first, by treating cervices liable to become cancerous, and thus prevent the formation of this neoplasm; and, secondly, to detect cancer of the cervix at a sufficiently early date to successfully eradicate the disease.

(1) It is the duty of the obstetrician to see each patient at his office from two to three months after her confinement, and there to examine and make a careful record of the condition of the pelvic structures, stating accurately what lesions have been produced by the confinement.

(2) Cervical lacerations should be certainly described, noting the position and depth of the tear and the appearance of the lips. Lacerations require no treatment when the lips are thin, uninfiltrated, and lie together. Thick, infiltrated, and everted lips associated with cervical catarrh call for depletory treatment followed by repair of the laceration.

(3) Every woman who has passed thirty-five years of age and has borne a child should have this examination made without delay by a competent physician, and if the cervical lips do not appear perfectly sound she should be kept under observation and examined at intervals of from six to eight months.

(4) Every woman over thirty-five, with a cervical tear, should be examined at least once a year for ten years, or longer, if the appearance of the lacerated area is not perfectly healthy.

(5) These rules apply with special force to patients whose family history shows a marked inclination to cancerous diseases.

If these rules are conscientiously observed, there is not a shadow of doubt but that thousands of lives would be saved in this country alone by timely interference with a disease so markedly local and accessible in its origin.

I feel that while we are searching for a cure for cancer, the line of progress in the immediate future for the gynecologist is clearly in the direction of prophylaxis and anticipation, either preventing or discovering the malady in its earliest stages.—*New York Medical Journal.*

New Uses for Guaiacol.

Diabetes.—Dr. Clemens, of Frankfurt-on-the-Main, reports favorable results in this disease from the administration of pure guaiacol, in the daily dose of from 18 to 30 drops, given in three doses, suspended in milk or codliver-oil. The patients were allowed to drink beer, and were upon a nitrogenous or mixed diet. At the end of eight days there was a notable diminution of sugar. After four weeks of treatment the patients were able to partake of some saccharine foods without increased glycosuria being produced. The salutary effect upon the polyuria was still more pronounced. At the end of several days of treatment the amount of urine passed in twenty-four hours had often diminished by one-half. The general condition was improved The drug was well borne.—*La Med. Moderne.*

ARMY AND NAVY.

CHANGES IN THE U. S. ARMY FROM AUGUST 5, 1894, to AUGUST 28, 1894.

A board of Medical Officers to consist of
Major Valery Havard, Surgeon,
Major John Van R. Hoff, Surgeon,
Major George A. Torney, Surgeon,
is by direction of the Secretary of War, appointed to meet at West Point, N. Y., August 15, 1894, or as soon thereafter as practicable, for the physical examination, of the cadets of the 1st and 3rd Classes; the cadets of the 2nd Class on their return from furlough and such other cadets of the Military Academy and candidates for admission thereto as may be ordered before it.

Leave of absence for one month, to take effect about August 5, 1894, is granted Captain W. Fitzhugh Carter, Assistant Surgeon.

Captain Wm. J. Wakeman, assistant surgeon U. S. Army granted one months leave absence, on completion of his duties at Fort Thomas, Rifle Range, Ky.

Leave of absence for one month to take effect upon the completion of his present duty at the Fort Thomas Rifle Range, is hereby granted to Captain William J. Wakeman, Assistant Surgeon.

Major Curtis E. Price, Surgeon, upon the expiration of his present leave of absence, is ordered to Fort Supply, Oklahoma Terry, for duty at that station, relieving Captain Wm. H. Corbusier, Assistant Surgeon. Captain Corbusier on being relieved by Major Price, is ordered to New York City, N. Y. for duty as Attending Surgeon and Examiner of Recruits, relieving Captian Wm. C. Shannon, Assistant Surgeon. Captain Shannan on being thus relieved, will report in person to Col. C. H. Alden, Assistant Surgeon General, president examining board, for examination for promotion.

Captain Edgar A. Mearns, Assistant Surgeon, will be relieved from duty with the commission appointed for the location and marking of the boundary between Mexico and the United States and ordered to Fort Myer, Va. for duty relieving Captain John L. Phillips, Assistant Surgeon. Captain Phillips on being thus relieved, is ordered to Fort McKinney, Wyo. for duty at that post relieving Captain George E. Bushnell, Assistant Surgeon. Captain Bushnell on being thus relieved ordered to Davids Island, N Y., for duty relieving Captain Samuel Q. Robinson, Assistant Surgeon. Captain Robinson, on being thus relieved, ordered to Philadelphia, Pa. for duty as Attending Surgeon and Examiner of Recruits.

NEWS AND MISCELLANY.

Program of the Nineteenth Annual Meeting of the American Academy of Medicine "Waumbek" Jefferson, N. H., August 29 and 30, 1894.—The Profession is Cordially Invited to Attend.

OFFICERS.

President: George M. Gould, Philadelphia.
Vice-presidents: C. C. Bombaugh, Baltimore; J. McFadden Gaston, Atlanta; S. W. French, Milwaukee; C. W. Foster, Woodford, Me.
Secretary and Treasurer: Charles McIntire, Easton, Pa.
Assistant Secretary: Edgar Moore Green, Easton, Pa.
Council: The Officers Ex-officio, and Traill Green, Easton, Pa.; Henry O. Marcy Boston; Benjamin Lee, Philadelphia; Albert L. Gihon, U. S. N.; R. Stansbury Sutton, Pittsburg; Frederic H. Gerrish, Portland, Me.; Leartus Connor, Detroit; Samuel J. Jones, Chicago; Theophilus Parvin, Philadelphia; P. S. Conner, Cincinnati; Justin E. Emerson, Detroit; Bayard Holmes, Chicago; W. T. Smith, Hanover, N.H.

Wednesday August 29th,—The program is arranged for the day, a recess will be taken, upon motion for dinner; and should there not be time, the papers not read will be read on Thursday before the papers assigned for that day.

Ten a. m. business meeting. Open only to the Fellows of the Academy.
Reading of the minutes of the last annual meeting.
Report of the council.
Election of Fellows.
Appointment of a Committee on Nomination.
Treasurer's report.
New business.
Eleven a. m. (Or at the conclusion of the business meeting.) Open session for reading of papers.

Topic for discussion: "Some Problems Pertaining to the Medico Social Relations of the Dependents, Defectives and Delinquents."

I. Preliminary—1. "Charity Organization."—The president's address, George M. Gould, Philadelphia.
2. "The Retrogressives, what Produces them; Classification," Bayard Holmes, Chicago.
3. "The Importance of the Study of this Subject to the Profession," Charles McIntire; Easton, Pa.

II. The Dependents—4. "The Relation of Food Adulterations to the Dependent Classes," Henry Leffmann, Philadelphia.
5. "The Provident Dispensary in England." H. Webster Jones, London.

III. The Defectives—6. "The Blind," J. A. Spalding, Portland, Me.
7. "Assistance and Care for the Blind," Charles A. Oliver, Philadelphia.
8. "Prevention of Blindness," Benjamin Lee, Philadelphia.
9. "The Present Status of Legislation for the Prevention of Blindness from Infantile Ophthalmia," Lucien Howe, Buffalo.
10. "What agencies Conspire to Check Development in the Minds of Children," J. Madison Taylor, Philadelphia.
11. "Prevention of Insanity," Gershom H. Hill, Independence, Ia.
12. Senile Dementia and Testimentary Capacity," J. N. Whittaker, Cincinnati.
13. The Medical Service of the United States Pension Bureau," P. S. Conner, Cincinnati.

IV. The Dilinquents—14. "Physical training as a Reformative Agent," Helen C. Putnam, Providence, R. I.

RECESS.

Wednesday evening, 8.20—The "Reunion Session." Under the direction of the Committee of Arrangements.

Thursday, August 30th.—10 a. m. business meeting. Open only to the Fellows of the Academy.
Unfinished business.
Reports of committees.
New business.
At the conclusion of the business session the reading of papers will be resumed.

V. Miscellaneous— 1. "The Evolution of Surgery," George D. Hopkins, Brooklyn.
2. "Government Commission Instead of State License," J. D. Kelly, Providence, R. I.
3 "Report of the Committee on the Comparative Value of Academic Degrees.
4. The Qualification of a Physician," J. M. Myer, Danville, Ky.
5. "The Work of our Academy," Robert Lowery Sibbet, Carlisle, Pa.
6. "And to Every Man His Work," Frederic H. Gerrish, Portland, Me.

Installation of the president-elect.
Appointment of additional member of council.
Unfinished Business.
Adjournment.

MEMORANDA.

In order to permit a full discussion of the topics presented, the authors of papers have been requested to limit their reading to twenty minutes, regulating details to foot notes or appendices; in order to have an interesting discussion, the committee on program will move that the time of each speaker be limited to five minutes.

There will be a meeting of the Council at the "Waumbek" on Tuesday evening August 28th, at which time the applications for membership will be examined in order that they may be reported to the Academy. It will facilitate their labors if the applications are sent in early to the secretary.

THE
MEDICAL AND SURGICAL
REPORTER.

No. 1957. SEPTEMBER 1, 1894. VOL. LXXI—No. 9

ORIGINAL ARTICLES.

POLARITY IN RELATION TO CATALYSIS AND VITAL ACTION.

J. F. PEAVY, M. D., POLLARD, ALA.

In an article in the REPORTER of July 7th, 1894, I have endeavored to present a theory as to the physiological functions of coloring matters and ferments. In that article the attempt was made to show that these substances are concerned to an eminent degree in the transformations of matter and transmutations of force effected by organic forms. The theory that their action hinges upon a capacity for polarization, while not receiving definite statement was distinctly implied. To further develop the idea of polarity in relation so catalysis and vital action is the object of the present contribution. My apology for offering it is my strong conviction that it will prove a key to some of the problems which confront the investigator in the region of chemico-physiologic research; questions of great interest to every wide-awake and progressive physician.

The terms *magnetized*, *polarized*, *nascent* when used with reference to atomic or molecular states, express the same condition. It is a condition of *heightened* activity, of *accentuation* of existing affinities. It represents a definite expenditure of force and is capable of evolving a definite amount of force. This state established, determining conditions decide what the resultant action shall be. If the proper conditions be present, the force propagates itself as electric currents. If answering chemical bonds are within reach of the excited affinities, chemical union results. Should the conditions for conduction or chemical action be wanting, static electrical conditions are established.

Let the condition be induced in a substance susceptible of a distinct bipolar excitation, as the magnetic metal iron, and a magnet is formed. If the iron has been previously hardened into steel and its molecules thus rendered less movable, the magnet, formed with greater difficulty by a greater expenditure of force, will be permanent. A permanent magnet is an aggregation of molecular magnets having a fixed axial relation to each other. It is itself a static condition of force, arrested motion, yet it embodies a capacity to take up mechanical motion and convert it into other modes of force. This capacity has been turned to immense practical account in the magneto-electric machines of late years. The capacity to transmute mechanical motion into electro-chemical force is possessed by each molecule of a magnetic substance in a condition of excitation. The aggregation of molecules simply aggregates the force.

The forces electricity and magnetism are directly and distinctly correlated. They have the same basis in a condition of molecular polarization. They are inseparably associated though acting in lines perpendicular to each other. To excite a molecule electrically is to excite it mag-

netically in a direction transverse to the line of electrical excitation. To magnetize a molecule in a given direction is to electrize it in a transverse direction.

Catalytic agents are said to act by their *mere presence.* This, of course, to a logical mind, is a luminous absurdity. Mere presence is a very negative property, yet these agents effect very positive results. They effect definite transformations of matter and transmutations of force. How do they act? By virtue of a capacity for polarization, they appropriate force and expend it in producing chemical decompositions and recompositions. The force is represented in the *condition* of polarization, and is transmitted by inducing a corresponding condition in the atoms of substances upon which it is expended. It expresses itself in repulsions between atoms in analytic processes, and in attractions and unions between atoms in synthetic processes. The force appropriated may be mechanical motion, acting through its molecular expression, heat, or those modes of motion known as light and electricity, in processes which involve a *consumption* and *storage* of energy; or, on the other hand, it may be chemical affinity in processes which involve a liberation of force as heat or motion. The principle of the conservation of energy is in no sense contradicted, since it is affirmed in no case that force originates *ad initio* but is always *derived* and always *transmitted.*

It is not intended, however, to set forth the contention that *all* the force concerned in every chemical action brought about through the polarizing action of a catalytic agent, is derived through that agent. This is probably true of all those actions which involve a *storage* of force. In the separation by chlorophyl of the atoms of O and C in the compound CO_2, and of O and H in H_2O where fully satisfied affinities are divorced, this is unquestionably true. In this case *all* the force that could be developed by the recombination of these atoms has been derived through chlorophyl from the sunlight.

In *force-evolving* actions brought about by catalysis, the force set free may be vastly in excess of that employed in producing the polarization, the excitement of affinities which initiates the actions. The polarization itself, however, represents a definite expenditure of force which reappears in the resultant action. Nevertheless, in every polarized atom there is besides the accentuation of affinity, a residuum of force-evolving capacity inherent in its nature, pertaining to its atomic *weight.* Even this may be regarded as an *induced* condition by introducing a consideration speculative, to be sure, yet reasonable. "The periodic law" of Mendelejeff affirms that the properties of the elements are functions of their atomic weights. In the light of this law and the principle of the conservation of energy, may it not be that the generic differences of the elementary forms of matter as expressed in their atomic weights, represent the effects of the operation of forces which have differentiated them from a single primary form; and that the sensible expressions of force, the dynamic states of matter, are evolved from a tendency to fall to a common level, to approach a common condition of static equilibrium.

The chemical actions of organic life involve either a storage of energy or an evolution of energy. In the ascending series of actions, force is stored in compounds formed through the action of polarity in chlorophyl, and certain other chemical bodies, called ferments, concerned in constructive metabolism. In the descending series of actions this force is released through the action of a complementary set of bodies which introduce oxygen and tear down the compounds built up through the action of the former. No organism can be built up or torn down without the action of some of these agents.

In the article referred to in the beginning of this paper, I ventured to regard the coloring-matters, chlorophyl and hæmoglobin, as well as the coloring of bile, as catalytic agents. It appears to me that they are *distinctively* catalytic agents, and on account of their relations to life, possess a peculiar importance. Through the operation of polarity in chlorophyl, materials are drawn from inorganic nature, out of which organic forms are built and forces are appropriated which are ultimately transmuted into vital action.

The *modus agendi* of chlorophyl presents itself to my mind as a distinct mechanical process, analogous to that of the magneto-electric dynamo. In this machine, rotary motion being communicated to magnets, there is developed in bodies having proper relation to them, a condi-

tion of polar excitement. The proper means of conduction being provided, this force is conveyed away as electric currents. Chlorophyl contains the metal iron which, placed near the middle of the electro-chemical series, possesses both acid and basic affinities and a peculiar capacity for bipolar accentuation, being hence distinctively magnetic.

The most refrangible rays of the sunlight, the violet and ultra-violet, the actinic rays, are employed in producing and maintaining a condition of magnetization and its correlate, electro-chemical excitation, in the iron of chlorophyl. The least refrangible rays, the red and ultra-red, the dynamic rays, are employed in conveying motion to the atoms or particles of magnetized iron. Thus are developed and maintained what are essentially rotating magnets. Through their action the vibratory motion of sunlight is absorbed, appropriated and converted into electro-chemical force, a dynamic force changed to a chemical action.

To bring our facts and theoretic conceptions concerning the action of haemoglobin into logical relationship, a different mental picture becomes necessary. Here chemical conditions and chemical actions are developed into dynamic expressions. In the lungs, the alkalinity of the blood is highest from the exhalation of carbonic acid, and the iron of hæmoglobin is in the condition of electro-positive accentuation. In this condition it seizes with avidity upon oxygen, which is electro-negative. In the capillaries of the various organs and tissues of the body, the alkalinity of the blood is lowest from the absorption of carbonic acid.

Here the iron of haemoglobin becomes electro-negative and throws off its oxygen. This oxygen, liberated in the nascent condition, unites with oxidizable substances present and generates *heat* and *motion*.

The atoms of C and H liberated from CO_2 and H_2O through the action of chlorophyl, represent the force used in separating them from their compounds at its highest degree of *tension*. They embody the capacity of evolving the *whole* of the solar energy they represent. This may occur directly in the process of combustion as a high expression of dynamic action or more slowly in the oxidations of animal and vegetable life.

In the high-tension, violent, uncontrolled action of combustion, *direct* affinities operate, but in the low-tension, even, *regulated* oxidations expressed in vital action, the presence and activity of these substances, coloring matters and ferments, which I have ventured to consider as intermediary bodies, become necessary. Fatty matters, to be sure, represent a condition of partial oxidation with lowered tension, yet of all the hydro-carbonaceous material utilized by animals they approach most nearly the condition of pure hydrocarbons and possess the highest capacity of heat production. It may be also that their oxidation constitutes an exception to the above statement, since, reduced to a finely divided "molecular" condition, they may be *directly* oxidized, especially in the lungs where the oxygen supply is abundant. This may constitute a special provision for heat production at this point, since heat is rapidly lost here in producing the difference in temperature between inspired and expired air, and also absorbed by the expansion of gaseous bodies which pass out with the expired air.

The carbohydrates, starch and sugars, those substances which exhibit so beautifully the marvels of magni-crystallic action, also display most strikingly the operation of polar agencies in animal and vegetable processes. Starch, $C_6 H_{10} O_5$, the first easily demonstrable product of the recompositions which follow upon the dynamolytic action of chlorophyl, may be regarded as the storage form of carbohydrate material. Under this form it is stored in the stems, cavities, seeds, tubers, etc., of vegetables, and in the liver of animals, for future use. In order to become available, it must be converted into the more soluble forms of dextrine and sugar. This transformation is effected by diastase and its congeners, the other diastatic ferments. To initiate these actions a certain degree of *heat* is necessary, which acts by inducing in the ferment a condition of accentuated affinity for water, the presence of which is also necessary that these actions may go on. The water is transferred to the material undergoing change and effects its hydration with evolution of heat. The heat may reach quite a high degree, as when large quantities of malting grain are contained in vats. In the germination of seed in a normal way, the heat evolved is no doubt in part applied to the constructive needs of the springing life.

The conversion of starch into sugar, while it confers a distinct gain in crystalline quality, solubility and diffusibility, involves a loss of heat and consequent lowering of tension. The lowering of tension is, however, for the purposes of life a distinct gain, since it confers a greater facility for being controlled or regulated in its heat evolving function. The control of the body temperature, the regulation of the heat producing, distributing and dissipating functions, so as to maintain a uniform normal, is one of the most remarkable powers of the animal organism.

The appropiation and transferrance of H_2O by diastase in accomplishing its function, presents us an analogy to the assumption and conveyance of O by hæmoglobin. May not also the difference between the so-called *latent* and *active* conditions of diastase bear an analogy to the difference between reduced hæmoglobin and oxyhæmoglobin?

The coloring matter of bile has imposed upon it a double work. It acts as a carrier both of water and of oxygen. During the period of digestion and absorption, while glucose is being deposited in the liver as glycogen, and peptones undergoing conversion into blood albumen, the bilirubin newly extracted from dead blood cells, appropriates water from the former and oxygen from the latter, to be yielded up in the oxidations and hydrations going on in the alimentary canal. During the intervals of digestion, the coloring of bile absorbed from the intestine in the condition of bilirubin, is converted in the portal vein into biliverdin, and upon reentering the liver yields up its water to convert glycogen to glucose, and its oxygen to complete the oxidation of certain nitrogenous bodies into urea.

The difference between the two conditions of the coloring matter of bile is not strictly a molecule of water and an atom of oxygen, H_2O+O, but a molecule of peroxide of hydrogen, H_2O_2. The same bond that links the H_2O and O to the coloring matter, links them to each other, and is broken at both points at the same instant. Bilirubrin cannot appropriate water unless oxygen be present, nor can it appropriate oxygen save water be present. To hold the one it must have the other.

Although the processes we have been considering are expressions of cell activity, cell life, it does not follow that any new force is originated by the cells themselves. Cells, like all aggregations of matter endowed with life, exercise *directive agency* over forces already existing. They select, combine, *direct* matter and forces drawn from the common stock in nature.

It may be objected that the agents of the destructive transformation, fermentation and putrefaction, which take place in dead organic material are organisms, and that the changes they effect are dependent upon their nutritive actions.

It will readily be admitted they are organisms, yet the fact remains that they are exceedingly simple in structure and the transformations they effect, while incidental to the nutrition and growth of the cells, are in themselves simple chemical reaction over which they exercise *directive agency*. They are able to disturb the balance of chemical attractions in the compounds which they tear down, only when supplied with a moderate degree of heat which acts no doubt by polarizing, that is, by increasing the chemical activity of their nitrogenous constituent.

It is a fact worthy of note that all the catalytic agents, so-called, concerned in organic actions contain the negative element nitrogen. May it be that this element, weak in its own attractions, unstable, fond of change, taking part in the most active phenomena of life as well as the most violent reactions of inorganic chemistry, facilitates the intra-molecular changes necessary to the discharge of their functions by serving as a centre or hinge about which the atoms may move and change their groupings without the molecule itself going to pieces?

Anesthetics in Labor.

Dr. M. M. Latta, in *North American Practitioner*, says: For many years I have given in all midwifery cases a mixture composed of chloroform, one pound; nit. of amyl, one drachm; mixed and well shaken it is ready for use. I found it especially useful in cases of weak heart as indicated by purple lips sighing respiration, and feeling of impending trouble. I generally precede its use by an opiate, in the manner and form that seems indicated.

THE MEDICINAL TREATMENT OF GRANULAR CONJUNCTIVITIS.*

CHARLES ZIMMERMANN, M.D., MILWAUKEE, WIS.

I have been asked by our chairman to read a paper on the medical treatment of granular conjunctivitis. This, however, is a very difficult task, especially in answer to the question, which is the best treatment of granulated lids.

Perhaps in no other eye disease have so many remedies or plans of treatment been designed as in the one under consideration. This fact alone would throw a critical light on the matter, according to the law, "the more numerous the remedies, the less curable a disease." But we get even a much more unpromising view if, looking over the galaxy of methods and procedures from the onset of historical ophthalmology up to our present times, we come to the conclusion that we have turned in a circle and are now with our end at the starting point of our medical ancestors of more than 2,000 years ago. For what else is it than the same principle when they used verdigris and we sublimate, or when Hippocrates scraped the conjunctiva in order to remove the granulations, practicing ophthalmoxysis, and we do the same thing but call it *brossage* or *grattage* of the lids? Nevertheless the subject is very important considering the devastation caused by trachoma, especially in the countries of its predilection. And a man who could entirely cure trachoma would do a greater service to humanity by that than by operating on cataracts.

The definition of granular conjunctivitis in the use of many not being very sharp, comprises collectively also much lighter forms of inflammation of the conjunctiva. Accordingly the reports of curing trachoma must be taken very cautiously. However, it cannot be denied that almost anybody who has had occasion to treat the disease, has met with good results by different kinds of treatment. If we consider the time not too short to form an opinion, it seems that a judicious revival of the old mechanical methods, combined with proper medicinal treatment, marks progress, especially in regard to the speediness of a cure. It is impossible to here review all the substances which have been tried with more or less success, and it will suffice to mention only a few which have been lately devised and have come into more general use, or have deserved more interest.

In 1882, de Wecker reported very favorably the action of jequirity on trachoma. I witnessed the cases treated by Prof. Knapp in 1883 and 1884 (*Arch. of Ophth.* XIII., 1 and 2), while assistant at his clinic. Three per cent. infusions were repeatedly brushed over the everted lids, three times a day and oftener, and if these did not act, five per cent. infusions were used. The consequence was swelling of the lids, increased congestion, and muco-purulent discharge. In some cases, however, it amounted to a development of a severe diphtheritic conjunctivitis, followed by pyorrhœa and more or less destruction of the cornea. The conclusions were (*l. c.*): that jequirity cures trachoma more quickly, but less safely than other remedies. Its action is highly beneficial in most cases, but neither uniform nor always controllable. Knapp recommended a restriction to cases of old, intractable pannus with advanced cicatrization of the conjunctiva which cannot furnish nutritive material enough for either an infiltration into the depth of the conjunctiva or for an abundant purulent secretion. Some (Coppez, Murrell), still use the infusion. Cheatham (*Ophth. Rec.*, 91) powders it on the conjunctiva in cases of severe trachoma with pannus, making from three to six applications. He watches the patient very closely during the jequirity inflammation. C. Michel (*Arch. of Ophth.* XXI., No. 3) recommends it again, if used carefully.

At a meeting of the Heidelberg Ophthalmological Society, 1891, (*Bericht*, 1891,) von Hippel published his experience, gained on over 300 cases of trachoma, with the method of the Doctors Keinig of Soest, which consists in rubbing the conjunctiva with pledgets of cotton dipped in sublimate solution, 1:2,000, after instillation of cocaine. (In the Transactions of the Wisconsin State Medical Society, of 1891,

* Read at the Wisconsin State Medical Society, May 2, 1894.

p. 117, I recommended it myself after some trials.) This rubbing has to be done gently when the conjunctiva is swollen and loose, in order not to cause ulceration. If the follicles are hard and the mucous membrane anemic, it has to be executed more forcibly so that the contents of the follicles may be expressed. The reaction is not very severe. Generally the conjunctiva swells and, the next day, shows a greyish coating which comes off easily. The follicles disappear gradually, without shrinking of the conjunctiva. There is a marked improvement of the corneal infiltrations and superficial ulcers which were produced by the trachomatous process, but not so, when associated with intense hyperemia and iritis. After the subsidence of the follicles the remaining conjunctivitis ought to be treated with astringents. Not in all cases was a lasting recovery attained. Relapses occurred in 15 per cent., which however ceased after renewed treatment. This procedure may be warmly recommended for severe cases with diffuse lymphoid infiltration of the conjunctiva. Its value seems to lie in the fact that the mechanical effect is enhanced by the use of sublimate. Bærenstein explains it thus: by the pressure, the follicles are destroyed and absorbed, and the sublimate abolishes the microbic agent of trachoma. Therefore it is applied with good success after the different operations of Sattler, Darier and others. Michel uses it with vaseline, with which he practices massage. Rosmini applies sublimate solution 1:2,000, or weaker, with an irrigator to the affected mucous membrane for 30-60 seconds; semi-biniodide of mercury in the same way. Pedrazzoli uses sublimate in a spray. Falta constructed a special forceps, with which, as cotton holder, the massage with sublimate can be done more thoroughly on all parts and recesses of the conjunctiva. Trousseau found pumice stone soaked with sublimate solution very effectual, and Stephenson touched the lid with a stick composed of one part sublimate and five parts chloride of potassium.

Massage has been used quite extensively with the following powders: boric acid, tannic acid, alum, iodoform, antipyrine; or with ointments of yellow oxide of mercury, iodide of potassium, creolin, resorcin, iodoform, or naphthol in combination with vaseline or crude kerosene oil. Solutions of pyoctanin, creolin, carbolic acid, naphthol, some in permanent irrigation, have been recommended. Blue mercurial ointment has been rubbed on the skin of the lids.

Another method is the subconjunctival injection of iodine solution or other solutions. Schnabel does not treat the granulations at all, only the accompanying inflammation by the constant application of icebags, and afterwards he uses caustics. The destruction of the follicles by actual and potential cauteries, as well as by electrolysis, belongs rather to the surgical department.

If we compare the different remedies in regard to their efficiency, sublimate seems to hold the principal place.

Nevertheless it is quite interesting to see how the various authors and inventors of new applications, in case of failure, or for after treatment, returned to the caustic and astringent methods with nitrate of silver and sulphate of copper, which have been so long in vogue. Only a long time of careful observation will decide the real value of a remedy, since many of them will only act so long as they are fashionable. Medicinal treatment of trachoma cannot be done away with entirely, but the operative treatment will predominate.

Erysipelas Toxines for Sarcoma.

Coley (*Am. Jour. of the Med. Sciences*) reports upon the results obtained by injections of the toxines produced in cultures of the streptococcus of erysipelas in twenty-five cases. Six he regards as cured, one still remaining under treatment, the others having remained well from three months to almost three years after the cessation of treatment.

He concludes: The curative action of erysipelas upon malignant tumors is an established fact. This action is much more powerful in sarcoma than in carcinoma. This action is chiefly due to the toxines of the erysipelas streptococcus, which may be isolated and used with safety. This action is greatly increased by the addition of the toxines of the bacillus prodigiosus. The toxines to be of value should come from virulent cultures and should be freshly prepared. The results obtained from the use of toxines without danger are so nearly or quite equal to those obtained from an attack of erysipelas, that inoculation should rarely be resorted to.—*Polyclinic.*

THE COLD PACK AS AN ANTIPYRETIC.

J. R. CASE, M. D., WORCESTER, PA.

I wish to call attention to a remedy that is as old as our noble profession, having been used by Hippocrates himself; a remedy that has lately claimed the attention of the profession and deservedly, as it is at once a safe, simple and very efficient means of reducing the abnormal temperature of the body. It is the most distinctive of hydropathic appliances, and may thus be described:

Have a blanket spread upon a bed or crib, as the case may be, and then wring a sheet out of cold water, say at a temperature of 60° F. In the case of a child the sheet should be folded several times, and for the adult use two sheets. Spread the sheet over the blanket and upon it lay the patient, and fold sheet and blanket quickly over him. Then apply comforts or blankets tightly around the patient to exclude all air. The heat of the body acting on this damp linen almost immediately generates vapor, and the patient is very soon in a warm vapor bath.

The effects upon the body of a febrile patient must be very plain. It is a simple philosophical process in which the heat of the body is transferred to the cold water in the sheet by simple conduction. At the same time that the temperature is thus being reduced, the pores of the skin are being thoroughly cleansed and thereby better fitted to perform their important functions. The equalizing thus of the temperature over the entire body, equalizes the distribution of the blood through the system, thereby relieving congestions whenever occurring—as experience amply testifies. Lastly it slows the heart beats, reduces the arterial tension, allays nervous irritability, reduces the respiratory movements and produces a feeling of well-being in the patient. I have seen cases that could not be quieted by any ordinary means, fall into a peaceful slumber almost immediately after being put in a cold pack.

Its advantages over internal antipyretics are many, as must be apparent to even a casual observer. It can be quickly applied and as quickly removed, the effects being under our complete control, for as soon as the temperature is within bounds we withdraw the remedy and the effects cease. It is also available in cases where it is utterly impossible to use internal medication, as I hope to show subsequently. It is safer because it depurates the blood instead of disintegrating it, as do many if not all of the coal-tar derivatives when used in efficient doses, as is evidenced by the accumulation of waste products in the blood, notably CO_2.

We know that pyrexia produces a hæmolysis and rapid transformation of the latent or potential energy, which becomes manifest as heat. Therefore, to conserve this energy, we must reduce this temperature quickly, safely and pleasantly. In the cold pack we have a remedy that fulfills all the requirements, then why should we resort to internal antipyretics of the limits of whose destructive, or deleterious action we know little. I do not wish to relegate modern antipyretics to oblivion, for I think they have a very useful field, which, however, is limited. Experience has taught me that their prolonged use is dangerous and very unsatisfactory, and I think they should be replaced by the cold pack in all cases of prolonged pyrexia.

Dr. G. N. Davis, (*Med. Age.*), declares antipyretic drugs are of value only as nerve sedatives. He declares cold the best of all remedies for the reduction of temperature. With the latter statement I thoroughly agree; with the former I cannot fully concur.

I have had recourse to the cold pack in upwards of fifty cases during the past two years, all of which were desperate ones, all other means having been exhausted before I was permitted to use the pack.

Fully 90 per cent. of the cases recovered, and I do not think that 20 per cent. could have done so without the pack.

The more fully to illustrate my views and substantiate the philosophical basis of the treatment, I will cite a few cases as they occurred in practice.

CASE I. I was called, Feb., '93, to see E. A., a child aged 5 years. I found him in a tetanic spasm; respiration 12 per

*Read before the Montgomery County Medical Society, July 11, 1894.

minute; jerky and irregular pulse almost imperceptible; temperature in axilla 104°; eyes turned up and patient *in extremis*. I used the cold pack, and in half an hour the child was breathing easily; pulse 160, temperature 101°; still some twitchings. I repeated the pack for fifteen minutes longer, when the temperature was 99.5°. and the patient was sleeping quietly. The pack was again used in four hours, and the temperature was easily controlled with small doses of phenacetine. Diagnosis *Meningitis*. I gave him Tinct. Digitalis, and Fluid Ext. Ergotæ, alternating with phenacein. After having his bowels acted upon, I had continuous cold applied to the head

At the end of a week he was convalescing. His left side and particularly his left arm was partially paralyzed, as was also his speech.

CASE II. Walter G., child aged 7 months, was taken sick in July, 1893, with a severe attack of iliocolitis, from which he recovered with the usual treatment, but was very weak and emaciated. In about a week after this attack he was taken with intermittent fever, which continued for two weeks. I prescribed quinine by mouth and rectum, but in spite of everything the temperature would run up to 104° or 105°, and the child was approaching an extreme condition. So much so, that I thought he could not recover. I used the cold pack whenever the temperature ran above 101°.5, and the child became restless, with the effect to reduce temperature and quiet the child; he usually passing into a quiet slumber. He was unable to raise his head for one week after the subsidence of the fever. His pulse had been very feeble, and his surfaces withered; generally he had a chill about 5 A. M., when he was blue and his hands cold, friends thinking he was dying until they became accustomed to seeing him in that condition. He made an uninterrupted recovery under tonic treatment.

CASE III. I was called May 5, 1894, to see Walter G., aged 2 years, 8 months, and found him with high fever, temperature, 104°.5; stupid. I saw him in the evening and he had complained all the afternoon. I looked upon the case as one of malarial intoxication and prescribed quinine suppositories and small doses of phenacetine, and expected to find him better in the morning. I saw him again at 11.30, May 6th, when he was in a spasm and unconscious, his parents thinking he was dying. His pupils were dilated, pulse 90, respiration 60, temperature in axilla, 107°.4. The case seemed hopeless. However, I used the cold pack, using water at a temperature of 56°, and had it renewed every 15 minutes. In half an hour the temperature had fallen to 104°, respiration 48, and spasm relaxed. I then left the patient, but ordered pack changed every 15 minutes until seen again, which was in two hours. Then his temperature was 99°.5; pulse irregular and intermitting 160; respiration 36; hands and feet cold. I ordered him wrapped in blankets and bottles filled with hot water applied to the feet.

℞ Nitro-glycerine..... gtt.ij.
Digitalis..... gtt.ss.

Sig: Every hour for three doses, and then every two hours until seen.

Gave quinine suppositories of 10 gr. each. The child was now conscious and asked for some food when milk was given and he drank of it. The temperature ran up to 103° at 6 P. M., when the pack was again used, and he rested well all night. 6 A. M. of May 7th, the pack was used again. The pack was changed three times at intervals of 15 minutes. The temperature had been 102°.9 (previous to which he had a chill) reduced in three-quarter hour to 99°.5.

On May 8th, the temperature was 99°; resp. 24; pulse 120, regular. May 10th, temperature ran up to 104°.5 at 1.30 A. M., pack was used, and at 3.30 A. M. temperature was 101°.5; at 5 A. M. temperature was 103°.9, pack used. Temperature 102°.5 at 7 A. M. At 9 A. M. 100°.9. At 12 M., 99.5°, pulse 116. From this time on he made an uninterrupted recovery.

I have used the pack with the most gratifying results in pneumonias of children when there seems to be an inevitable dissolution.

I trust I have said enough to bring the treatment before you in a way that may cause you to at least consider it a valuable therapeutic means if you have not already done so.

DR. BOUCHARD says that a simple and easily applied means of recognizing in a certain and indubitable manner the presence of death is by noting the temperature found in the armpit. If it descends below 68° F., it is a positive sign of death.

COMMUNICATIONS.

EARLY DIAGNOSIS OF CANCER OF THE UTERUS.*

EDWIN RICKETTS, M. D., CINCINNATI, OHIO.

It is not my intention to ask you to consider the latest discovery of a startling nature in pathology by "trotting out" another little beast of a formible appearance, at least on the miscroscopical slide, with a personal desire that it might be added to the already extensive "Bacteriological Menagerie." Instead I bring for your consideration an old subject, trusting that the discussion may be fruitful in causing not a few earliest possible diagnoses, which I take to be the greatest and formost step in doing an operation, that when done early promises more than does a late operation.

Cancer of the uterus is abroad in the land, and every member of this society has had these cases referred to him by the attending physician, with both patient and physician desirous of as much comfort as possible by the prolongation of life, if a cure cannot be hoped for.

We have cases reported of early diagnosis of cancer of the breast, followed by prompt extirpation of the gland, with nonrecurrence even after five, ten, or more years. Why are we not to expect better results for as early an extirpation of the cancerous uterine globe, in which the disease is known to develop more slowly than in any other portion of the body?

We, as operators with some cause for complaint, say to the general practitioner, who sees these patients previous to consulting us, that we do not see them early enough to offer a procedure that promises the most in the way of relief, if not a cure; while the general practitioner has the best of the argument when he asks justly for more light—that is, how is he to see these cases earlier, and when once seen how is he to be able to make the earliest diagnosis?

1. Let him impress upon the minds of every adult married female that may consult him that cancer of the uterus is more liable to make its appearance between thirty-five and fifty years of age.

2. That a leucorrhæ followed by a watery discharge, that soon becomes red, and in time offensive, staining the linen a dirty, yellowish-red, are symptoms demanding prompt consultation with the family physician as soon as the first-named makes its appearance.

3. That he may have at his commaud three common and yet all-important aids. viz., those of sight, smell and touch. With these special senses properly educated, he seldom need be at a loss to make the required earley diagnosis. Such a practitioner will not make a hurried, casual examination through unloosed skirt-bands and attempts to excuse himself by telling the patient that she is "having her change of life," and will be all right soon.

With prompt action on the part of the patient and physician, operators can offer a cure in a number of cases by means of the vaginal or the combined hysterectomy, with a desired prolongation of life in the remainder.

The physician possessing a normal nose, one index finger, one middle finger, one or two eyes, is peculiarly fortunate as to expense, for they cost not a thing. True, they do not glisten so brightly, nor possibly do they impresel the laity so profoundly, as the attractive recently imported microscope that is so kaledioscopic, even in the hands of our trans-Atlantic myopic brethren, who are giving special attention to pathology as seen through the microscope. The operator should not attempt the work of the pathologist in connection with his work, nor should he be microscopist to himself.

For convenience we will divide the uterus into three sections.

1. The neck—that portion protruding from the upper end of the vaginal tube and into it, and which stands almost erect.

2. The attached—that tissued partition that separates the vagiual tube from the abdominal cavity.

3. The fundus—that portion of the uterus that lies within the lower portion of the abdominal cavity, save being covered by peritoneum.

Early cancer of the uterine neck can be felt and seen without dilatation of the uterine canal, in part or entire, and it can

* Read before the Obstetrical Society of Cincinnati, 1894.

be seen and felt near the beginning of the leucorrheal discharge; while cancer beginning in the attached or fundal portion is not recognized until the leucorrhea and watery discharge is accompanied by the smelling discharge, unless the uterine cavity has been dilated as soon as a suspicious discharge begins.

Cancer beginning in the cervix spreads more rapidly to the attached and fundal portion; beginning in the attached or fundal portion it spreads to the neck; this latter form is longer amenable to treatment.

In multiparous cervices cancer is more easily recognized, while trauma is credited as the main exciting cause. In the non-multiparous uterus, in which cancer begins at the attached or fundal portion, we can not consider trauma as the main cause. With the earliest possible diagnosis of cancer, be it situated in the neck, attached or fundal, or be it found in all three localities at the same time, pregnancy should not be entertained by the primary or secondary uterine possessor nor by the physician. Under such circumstances it becomes a highly offending member, just as much so as a cancerous eye, an osteo-sarcoma or a malignant mammary gland.

Cancer is a new growth, and in time breaks down; there is never any attempt at repair of the invaded tissue; it goes from bad to worse. There is a highly reddened condition of the tissue surrounding the growth, while the growth and surrounding tissue are tender and in a short time bleed easily when the probe, speculum or finger comes in contact with the same. The growth and surrounding tissue are engorged with blood, and when breaking down takes place depletion helps to reduce the size of the parts. The same is true with cancer located and breaking down in the attached or fundal portion.

Do what you may in internal medication with local application of remedies, the loss of tissue as the result of cancer is never to be replaced by healthy tissue. In the very early stage the membrane covering the suspicious growth is smooth, while beneath it and through it the sense of touch alone will reveal the character of the nodule that soon, if the uterus is allowed to remain, is to prove so serious. In the early stage of the developing nodule the membrane covering the same is of a pink-white color, while that covering the surrounding tissue is somewhat of a deeper red; pressure of any kind gives pain.

Cancer located on the neck may look and feel like hard or soft nodules, or granular erosions may surround the os externum, but it differs with cancer, as it has a soft edge, while the mucous membrane has high points scattered and gradually sloping around within the soft border; it bleeds easily, but does not slough, and with no treatment soon shows signs of repair.

The walls of a cancer nodule on the verge of breaking down are formidable, while its middle is depressed and the body catacomed, the result of sloughing.

In a follicular cervix the needle or bistoury will differentiate by a puncture of the follicles; you can rub any scarlet patch without causing the same to bleed.

Be the cancer located in the neck, attached or fundal portion, the first and second cardinal symptoms, those of leucorrhea followed by watery discharge, are present. Later, as the result of breaking down, the characteristic odor makes its appearance; with such a change of symptoms present, not complicated by a non-malignant polyp, cancer should be promptly diagnosed.

So soon as a leucorrheal discharge, with or without cancer of the cervix being made, followed by a watery discharge, with the first detectable odor that is not the result of non malignant polypus, vaginal hysterectomy, with or without the combined method, is the only procedure to be considered.

With a cancerous deposit in whicb the characteristic bloody, watery, bad-smelling discharge has existed from three to six months as a result of the breaking down cancerous tissue, nothing can be promised in a cure, but much can be promised in comfort to the patient, with possible prolongation of life, especially in cases where cancer begins in the attached or fundal portion of the uterus.

In the diagnosis of this disease, the microscopic aids have been disappointing —even misleading; if, under the present delayed early diagnosis of the uterus, as a result of depending too much and too long upon the microscope, we are to make our escape, it is to by intelligently *feeling* and *seeing* early, along with the earliest possible detection by *smell*.

TRANSLATIONS.†

TRACHEAL FISTULÆ.

In *Le Bulletin Medical* for July 1, 1894, Kirmisson reports the case of a young man 16 years of age while suffering with croup submitted to the operation of tracheotomy and was cured of his laryngeal disease. Since then he had been compelled to wear constantly his canula. As a result the boy prevented that rare condition a tracheal fistula. Kirmisson removed the canula and found that the boy was able to breathe without it without any difficulty; the external orifice of the fistula commenced to close, and 15 days after the removal of the canula when the boy was shown to the class a deep depression was found at the middle portion of the neck. At the center of this excavation was a small orifice irregularly ovoid, preventing a vertical diameter of 7 to 8 millimeters and a transverse diameter of 5 millimeters. Through this orifice could be seen the mucous membrane of the posterior wall of the trachea presenting a very pronounced reddish tint. The air passed freely through their orifice but on closing it resperation was not impeded through the natural channel.

This condition following tracheotomy is very rare. This is not, however, the only variety found. Fistulæ exist due to traumatism, particularly to knife-cuts in attempted suicide. In this case, the solution of continuity is situated high up; there is also found a laryngeal wound, and consecutive to this a laryngeal fistula. Military surgeons have described lesions of the same kind consecutive to gun-shot wounds, the ball producing a veritable loss of substance of the anterior wall of the trachea. In another class of patients we find tracheal fistulæ consecutive to suppuration of the larynx engendered by laryngeal tuberculosis or syphilis. After opening of the abscess, there is often discharge of the necrosed cartilage, the orifice does not tend to close, and instead under the influence of a prolonged suppuration its edges organize gradually and a laryngo-tracheal fistula is thus produced. The reason that fistulæ are rare after tracheotomy is due to the fact that the canula is as a rule not permitted to remain long enough to result in this complication. The conditions that necessitate a prolonged retention of the canula, are in the first place, paralysis of the vocal bands consecutive to diphtheria and opposing the passage of the air through the normal passages. Alongside of this cause, which is not very frequent, we find another which has been noted by a large number of surgeons, viz:—the production of fleshy polyp-like growths, at times quite voluminous, which form in the trachea and which, drawn in during inspiration, resist the passage of air. These are most common at the upper angle of the tracheal wound and on the posterior wall of the trachea at the point where the canula exercises a true permanent traumatic action. A third cause presenting the removal of the canula, and this is undoubtedly the most frequent cause, is the chronicity of the affection for which the tracheotomy has been practised. There exists thus a true obliteration of the larynx, as in certain cases of tuberculosis or syphilis of the larynx.

It may then be seen that tracheal fistula can exist in two different conditions. Either the larynx is free and it is the only lesion which should engage the surgeon, or else the fistula coincide with grave lesions of the larynx and trachea, and principally with a stenosis; in this case the situation of the disease is quite another. The *symptoms* of tracheal fistula are not numerous or important. There is generally in the median line of the neck a deep depression, a sort of infundibulum at the base of which a small orifice leads into the trachea. The skin is invaginated and becomes continuous with the tracheal mucous membrane. The dimensions of the fistula are generally small.

The operative procedures for the cure of tracheal fistulæ are numerous enough to permit of a classification as follows: 1. These processes of autoplasty in which there is dissected and used a flap of tissue in the vicinity of the fistula. 2. These processes in which there is simple employment of the skin without previous cutting of the flap.

These different operative procedures have all succeeded in some cases and failed in others. Kirmisson prefers the metho of Berger and Lehart.

THERAPEUTICAL SUGGESTIONS FROM FOREIGN JOURNALS.*

THYROIDINE IN MALIGNANT PRECOCIOUS SYPHILIS AND OBESITY.

Dr. J. D. Menzies (*La Semaine Médicale*, No. 43, 1894,) of the English Navy, has had occasion to treat several cases of malignant precocious syphilis, an affection which is particularly frequent amongst the Hindoos. The patients were cachetic, bearers of squamous, ulcerating and osseous lesions where the mercurials and iodides had been administered, in vain. The dry extract of the thyroid glands of sheep was given, in the form of tablets, 25 to 50 cgms. per diem, while all specific midication was suspended. In all these cases he obtained a more or less considerable amelioration of the local as well as of the general condition. The cutaneous and osseous lesions healed, at least partly, and the pigmentations following the skin lesions disappeared as well.

Another English physician, Dr. N. Yorke-Davies, of London, has discovered these same tablets to be a precious addition to the treatment of obesity. Thus in patients placed under both an appropriate diet and treated with thyroidine the decrease in weight was from two to three times greater by dieting alone.

TREATMENT OF INCIPIENT CONSUMPTION.

Prof. Potain (*La Rivista Clinica è Terapeutica*, No. 6, 1894,) speaks highly of the iodides in incipient pulmonary consumption, and especially in the following formula:

℞

Chloride Sodium	20	o (ʒv.)
Bromide Sodium	5	o (ʒjss.)
Iodide Sodium	2	o (grs. xxx.)
Water	200	o (ʒvjss.)

A teaspoonful two to three times a day in milk. If chronic catarrhal symptoms predominate, turpentine and tar preparations together with creasote may be found serviceable ; these will be harmful if the suggestion be intense. It is wrong to regard creasote as a specific in tuberculosis. The sulphurous mineral waters are also useful though these are rather appropriate to cases with gastric catarrh, without much tendency to congestion. The general nutrition deserves attention with especial predominence of fatty foods. Cod-liver oil is hence here indicated, though if not tolerated, milk and butter may replace it. For the night sweats the phosphate of lime, in large doses, especially of the insoluble preparations, is valuable; excellent results follow the administration of the neutral phosphate in doses of four, six or eight grains a day. The diathetic conditions should also be combatted. In syphilis, specific treatment; in arthritism, the salicylate of soda—in short, the indications will differ according to a diligent study of the symptoms of each case.

CALOMEL AND TRAUMATICINE IN SYPHILIS.

Dr. F. Cauchard (*La Semaine Mèdicale*, No. 43, 1894,) has recently tried a mixture of traumaticine with 25 per cent. of calomel in the treatment of syphilis. The patient after a bath has his eruptions, especially the more extensive ones, or, instead, the whole back be painted with this preparation. After evaporation of the chloroform—traumaticine consists of a solution of ten parts of gutta percha in ninety of chloroform—there remains a coating of varnish which is closely adherent to the skin. This is renewed three times a week, until the secondary manifestations have disappeared. After its use the secondary eruptions have been observed to disappear, in twenty to thirty days; it is especially in papular, pustular and squamous syphilides that it has been found valuable. This method has the advantage of enabling one to combine general with local treatment. It would seem particularly indicated in weakly subjects who cannot tolerate the internal use of mercury as well as in children with hereditary syphilis and in the management of late cutaneous manifestations.

CHLORIDE OF ZINC IN OTITIS MEDIA CRANULOSA.

Drs. Rottel and Montalescot (*Wiener Medizinische Presse*, No. 27, 1894.) recommend highly the chloride of zinc in suppurating inflammation of the middle ear, with granulations. Morning and evening the patient is to inject into the ear a syringeful of the following solution:

℞

Chloral	3	o (grs. xlv)
Borax	4	o (ʒj)
Destilled Water	1000	o (ʒxv).

This solution is both antiseptic and anodyne. Three to four times a week the

*In charge of the Translator, F. H. Pritchard, A. M., M. D.

granulating points are cauterized with a solution consisting of one gram of the chloride of zinc to thirty grams of water. A small tuft of cotton is wrapped around the tip of a probe and dipped into the solution is introduced into the tympanic cavity through an ear speculum. The sensation of resistance felt by the operator will show that the tampon has reached the wall of the cavity. The probe is then carefully turned around in order to touch all the diseased mucous membrane. The first cauterization will cause slight hemorrhage which will yeild to injections of warm water. The chloride causes a destruction of the granulations and a fibrous alteration of the mucous membrane and the remains of the tympanic membrane; a cure may be expected in three to four months, a relatively short time for such an obstinate disease. In cases where the granulations reach out into the meatus they may be removed with the curette or the cold snare and the bleeding surface cauterized with a 10 per cent. solution of the chloride and then the described method carried out. Treatment by this preparation of zinc is exclusively indicated in the granulating form of middle ear inflammation; it is contraindicated in the simple, hypertrophic and ulcerating forms.

TREATMENT OF HEMORRHAGE FROM THE BLADDER.

Dr. Poussond (*Wiener Medizinische Presse*, No. 29, 1894) offers several useful hints in the management of this symptom. He does not think that rest is indicated in all cases. If from a stone it is of course necessary, as the dorsal position often alone suffices to cause hemorrhage to cease; in other cases this position may favor congestion. As to drugs he recommends poultices containing opium to the region of the bladder, opium and belladonna internally, especially morpine subcutaneously to reduce the vesical irritability. Intra-vesical injections he would have entirely left alone as they cause coagulation and increase irritation. If they be required from urgency of the moment they should be given after evacuation of the bladder and those drugs favoring coagulation avoided. The choice of a styptic is not immaterial. Ergot causes contraction of the bladder and irritates the muscle fibres; matico, gallic acid and the preparation of alum containing iron, are preferable. In congestive hemorrhages of prostatic affections he much favors matico in infusion, in a daily dose of thirty grams. In profuse hemorrhages he employs gallic acid, in the following formula:

℞

Gallic Acid.....	1.0-1	5 (grs.xv-xxij.)
Syrup Opium		
Syrup Bitter Orange Peel āā	30	o (℥j.)
Distilled Water.....	60	o (℥ij.)

A teaspoonful every hour.

The ferric alum may be employed instead of gallic acid and in the same dose. Both of these remedies are powerful hemostatics and are only to be used after other means have failed.

A HOMEMADE MEAT POWDER.

Dr. W. R. Huggard (*Muenchener Med. Wochenschrift*, No. 25, 1894) gives a convenient method of preparing a powder from meat to be used on a nutrient. Lean meat is cut into small pieces; these are dipped for a few minutes into hot lard until the surface is browned, then taken out and allowed to drain on a sieve. They are then cut into fine pieces and dried in an oven for twenty-four hours with a slow fire. The meat thereby becomes dry and brittle and is easily ground in an ordinary coffee mill. By this process of roasting it has lost four-fifths of its weight. This meat powder has a very agreeable taste and a fine aroma. It may be administered in the most different ways as in hot water, as a tea, mixed with mashed potato, on bread and butter as a sandwich, with or without the addition of pepsin. It is very easily digested, tolerated by the most delicate stomach, and it may be kept, if dry and excluded from the air, for a long time.

LOCAL ANESTHESIA BY INJECTION OF COLD FLUIDS.

Dr. Létang (*Bulletin Médical*, No. 48, 1894) recommends subcutaneous injection of cold fluids for the production of local anesthesia. To reduce whatever fluid that may be used to the proper degree of cold he advises a mixture, by weight, of eight parts of sodium sulphate and seven parts of hydrochloric acid. A test tube c

taining a solution of common salt, (0.5-1 per cent.,) is placed in this fluid. If the temperature of the freezing mixture has sunken to 10°c, that of the salt water will be found to be 0°c. The syringe is filled with this and the injection made which causes neither pain nor induration at the place of injection, but a complete and long lasting anesthesia. Instead of this salt solution any other may be used which will reduce the temperature to o°c. He recommends the following as the best:

℞ Sterile Distilled Water
Pure Glycerine, āā..... 100 | o (℥ij ʒj.)
Ether..... 2 | o (gtts. xxx).

This mixture is easily kept, and may be employed even to ten injections at a time of ten grams each. It is quite sufficient for the requirements of ordinary practice. In a number of minor operations where cocaine is usually employed in extraction of teeth, removing of ingrowing toenail, amputation of fingers and toes, this method gave good results. Also in the treatment of obstinate neuralgias, of the trigeninus, intercostal and sciatic nerves the injections were successfully made into the region or the substance of the nerve.

GLYCEROPHOSPHATE OF POTASH IN NERVOUS DISEASES.

Prof. Jolly (*Muenchener Med. Wochenschrift* No. 25, 1894,) has employed the glycerophosphate for the last ten years in the treatment of all nervous diseases. As they are all dependent upon an augmented excretion of phosphates from the nerve-cells the treatment is according to him, quite simple and should consist in supplying phosphorous again to these tissues. The best form is the glycerophosphate of potash as this element is found in the nerve centres and elements.

TREATMENT OF ERYSIPELAS BY THIOL.

Dr. Rudneff of St. Petersburg (*Hospitals Tidende*, No.'19, 1894,) has obtained good results in erysipelas by application of a forty per cent. solution of thiol to the affected parts, five times a day.

EPILATORIES AS ANTISEPTICS.

Dr. Annequin (*La Semaine Mèdicale*, No. 43, 1894) has employed certain epilating substances as the hydrosulphate of calcium or the sulphate of barium to remove hairs and act as antiseptics where it is impossible to remove all the hairs by shaving and at the same time to render the part completely antiseptic as in operation on the perineum, the scrotum, etc. He adds the hydrosulphate of lime to water until it acquires a pasty consistence when it is applied to the region to by epilated. Epilation is complete in ten minutes, at least, without the least irritation or pain. The follicles are not destroyed for the hair will reappear after a few days. The sulphate of barium may be formulated as follows:

℞ Sulphide Barium,..... 10 | o (℥ijss.)
Powdered Starch,.....
Oxide Zinc, āā, ... 5 | o (ʒj¼.)

This powder should also be added to have water added until it forms a paste.

CEYLON CINNAMON AS A PALLIATIVE IN CANCER.

Dr. J. C. Ross (*La Semaine Mèdicale*, No. 43, 1894,) has found that the internal use of the bark of Ceylon cinnamon is an excellent palliative measure in the treatment of carcinoma of various internal organs; it must be given in large doses. He employs the following formula:

℞ Ceylon Cinnamon Bark.... 350—400.o. (ʒxj—xiij.)
Water..... 3 litres. (3 qts.)

Boil this mixture down to a quart. Decant without filtering. Take a pint every twenty-four hours by the half-glassful, preferably after eating. Shake the bottle well before taking.

This treatment has given him good results in carcinoma of the stomach, breast, tongue, rectum and uterus. The principal effect is to quiet the pain, decrease the odor and improve the general condition of the patient. With this treatment patients who have been for a long time under morphine have been able to dispense with this drug.

Must Have A Large Collection.

Edith—You ought to start a jewelry store.—*Chicago Record.*

CORRESPONDENCE.

"DO NOT TURN OUT THAT CLOT."

EDITOR OF MEDICAL AND SURGICAL REPORTER:—Your editorial "Do not turn out that clot," in the August 4th, number of REPORTER, struck me the more forcibly on account of an occurrence in my own practice a month ago.

I was called to attend a lady, who was as near a wreck from malaria poisoning and neglect as I ever saw. The first of a pair of twins came away all right, alive. I found the second one dead. On passing the hand I found the placenta was attached to the left side, and partly over the mouth of the womb, which had caused excessive hemorrhage. I ruptured the sac and placed the head in position, and the dead child came away. The womb contracted down to the usual size and I was congratulating myself, when, on examining, I found the womb nearly double its size of half an hour previous.

I made an examination and found but very little flow from the vulva; I had given nitro-glycerine and strychnia, as also ergotole. Whatever was to be done! I was afraid to meddle any more, so awaited reaction—pulse down to 20 beats and hardly perceptible, and respiration about the same. I thought I had a dead woman on my hands. Well, I waited half an hour. No one present but an ignorant old negro and myself. Gradually the pulse became stronger, then a little more frequent. I do not know how near a faint the lady was, because I did not look. She was perfectly limp; head on level with body. It was a dull half hour for me. But the rally was good and held all right. I applied hot cloths, etc., over abdomen, gave opiates and left seven hours after. My next visit, twelve hours afterward, found womb gradually reducing in size, and all doing well. I argued from the amount of blood lost from such a case (nearly a gallon,) it was best to let the clots alone—because the womb was hard, not flacid, and the clots would answer as a tampon.

Your editorial convinces me that in *this case* I had done the right thing. This is the first case of the kind that I have encountered. It makes me feel "queer" still, when I think of the hours I looked and waited at that time.

Fraternally,

BRODNAX, LA. BEN. H. BRODNAX,

CHRISTIAN SCIENCE.

EDITOR MEDICAL AND SURGICAL REPORTER:—In Dr. Longsderf's article on "Christian Science and its relation to the Medical Profession," in the August 11th, number of your JOURNAL, after admitting that there were thousands of instances of authentic cures on record as a result of christian science, she faces about and says "The importance of some definite restraining force for these abuses can scarcely be overestimated, and if public opinion and the advanced *philosophical science* of our era have been powerless to effect this, it would seem to come into the province of legislative enactment."

This is unjust, inhuman, selfish and cowardly. We would hardly expect one of the *gentler sex* of our profession to advocate such hard measures. We should not imprison our fellow-mortals simply because they effected cases that baffled our skill. "If ye have faith like a grain of mustard ye can remove mountains."

We are materialists. We look at our patients as mere machines. We forget that they are endowed with souls, (whatever that may be.)

We bow down and worship a lot of microbe resurrectionists, who were never in a sick room except that of dogs and guinea pigs, and have them dictate to us the quickest way to obtain a post-mortem.

To read some of the articles of our specialists, one feels that it is impos-

for any to die—and yet a glance at the death rate will reassure one that St. Peter is kept as busy as of yore examining passports. We should hail with delight any measure that has effected "thousands of cures," whether our dull minds can comprehend the rationale or not. For there is not an anatomist, or histologist, or physiologist, or neurologist living to-day who has a clearer insight of what *life* really *is*, than had the Father of medicine.

"There are more things in heaven and earth, Horatio, than are dreamt of in your philosophy."

Yours truly,

J. Newton Hunsberger,

Skippack, Pa.

A CORRECTION.

Editor Medical & Surgical Reporter:—I have just noticed an important error in the report sent you of my demonstration of "A new Method for Reduction of Fractures of the Lower End of the Radius" before the Philadelphia County Medical Society which recently appeared in your valued journal.

The second paragraph should read: "The surgeon stands in front of the patient and interlaces his fingers beneath the *pronated* wrist and palm of the injured member," etc., not "supinated wrist" as printed. As all that follows depends upon the wrist being in pronation.

Very truly,

Thomas S. K. Morton.

TREATMENT OF DYSMENORRHŒA.

After detailing the remedies usually employed in the relief of minor degrees of menstrual pain, such as antipyrin, phenacetin, codeine, etc., Schwarze remarks that in many cases of obstinate character local treatment is generally necessary. This, however, many patients are unwilling to undergo; and in the case of virgins it is very undesirable that they should be subjected to it. In that event, Schwarze mentions two modes of treatment of some value which have not received the attention they deserve. The first is the gymnastic treatment introduced by Thure-Brandt. It is necessary here to distinguish between dysmenorrhœa in which inflamatory processes are present, and that where they are absent. In the latter class, to which the menstrual pain of most virgins and sterile women belongs, this method is of particular value, whether anæmia or chlorosis be present or not. It is a general treatment of the body, though the movements recommended by Thure-Brandt for this purpose are limited to five, and are carried out chiefly with the lower limbs. These may be conducted at home by the patient's friends. If possible they should be performed daily, and in any case daily for a week before the expected menstrual period. The influence of bodily movement upon the lessening of dysmenorrhœa is shown by the beneficial effect of dancing and riding just before the onset of menstruation. The second remedy that is worth consideration in obstinate cases is the administration of viburnum prunifolium. Its action is narcotic, relieving pain and acting more particularly on the uterine nerves, and is of especial value in the non-inflammatory form. It may be given in the form of fluid extract, one teaspoonful three times a day for about a week before the expected period, and during it. It is not unpleasant to take, and is free from after-effects. In dysmenorrhœa associated with inflammatory changes it is of little use.—*Therapeutfsche Monatshefte.*

THE MEDICAL AND SURGICAL REPORTER

ISSUED EVERY SATURDAY

HAROLD H. KYNETT, A. M., M. D.
Editor.

PENFIELD PUBLISHING COMPANY
Publishers.

Asbury Park, N. J.—1026 Arch Street, Philadelphia, Pa.

TERMS:—Three Dollars a year, strictly in advance. Sent four months on trial for $1.00.

REMITTANCES should be made payable only to the Publisher, and should be made by Postal Note, Money Order or Registered Letter.

NOTICE TO CONTRIBUTORS:—We are always glad to receive articles of value to the profession, and when used they will be paid for, or reprints supplied, as the author may elect. Where reprints are desired, writers are requested to make a note of that fact on the first page of the MS. It is well for contributors to enclose stamps for postage, that the articles may be returned if not found available.

SATURDAY, SEPTEMBER 1, 1894.

EDITORIAL.

THE DETECTION OF TYPHOID IN WATER.

The communicability of typhoid fever by drinking water, has become one of the cardinal principles of sanitary science. On this account water becomes one of the efficient channels through which the virus of this most dreaded of fevers can gain access to the body. The possibility of the infection of water is readily understood when the fact is considered that typhoid bacilli will live in water for many days, thus being capable of a wide area of dissemination from the infected source. These facts and their direct bearing upon the occurrence and frequency of typhoid fever in certain localities, are well known to physicians and need not be discussed anew.

The importance, from a sanitary standpoint, of being able to detect the presence of these bacteria in water suspected of conveying them, is a matter both of interest and of controversy. It may be said that the most difficult feature in their detection is the differentiation of typhoid bacilli from the other bacteria, more especially *Bacillus coli communis*, which resembles them very closely in their morphological characters. A brief summary of the more important and practical methods for differentiating these bacteria and of detecting typhoid bacilli will be of interest.

Behavior in milk. Dunbar *Zeitschrift für Hygiene*, 1892, p 491,) has pointed out anew the difference in the reaction of these bacteria in milk. In sterile milk, the typhoid bacilli render the liquid slightly acid but never bring about its coagulation. On the contrary, *Bacillus coli*, at the temperature of the body, coagulates the milk in from twenty-four to forty-eight hours, at the same time rendering it strongly acid in reaction.

The production of gas. Smith (*Centralblatt für Bakteriologie W. Parisitenkinde*, xi (1892) p 367,) pointed out the fact that the typhoid bacilli when grown in bouillon containing certain sugars, in the fermentation tube, did not produce any gas, while the colon bacteria produced a large quantity of gas composed of CO_2 and H.

Uffelmann's Method. This method, described by Uffelmann (*Berliner Kli-*

Wochenschrift, 1891, No. 35, p. 827,) is based on the idea that very few bacteria can grow in a culture medium as strongly acid in reaction as can the typhoid bacilli. For the demonstration of this method the author used gelatin to which a definite quantity of citric acid (eight drops of a 5 per cent. citric acid solution to 10 c.c. of gelatin) and methyl of violet have been added. The typhoid colonies assume a blue color, which becomes more intense with their age, and is finally of a more deeper tint than the surrounding gelatin. By means of this method, Uffelman states that he was able to so far eliminate other organisms that a water, in which by using ordinary gelatin 12,500 colonies were obtained, when tested by this special method exhibited only nineteen. From another sample instead of one hundred and eighty, only eleven colonies appeared, and of these, six are stated to have been composed of typhoid bacilli. The method, however, has been shown to possess certain elements of disadvantage, as sometimes the typhoid bacilli fail to grow in it, and Dunbar showed that *Bacilli coli* will grow as vigorously as the typhoid bacilli in this medium.

Parietti's Method. This author found that typhoid bacilli were capable of growing in bouillon containing a considerable quantity of carbolic acid, while *Bacillus coli* and other bacteria failed to develop.

Frankland (*Micro-organism in Water*, 1894, p 273,) shows that the period of incubation must extend over at least forty-eight hours, especially when the number of typhoid bacilli is small. The solution used in the test is composed of five per cent. carbolic acid, and four per cent. pure hydrochloric acid in distilled water. From three to nine drops of this solution was added to each tube of 10 c.c. of bouillon. Vincent (*Compt. rend. Sciences de la Soc. de biologie*, 1890) endeavored to destroy bacteria other than typhoid, in water, by shaking it up with a five per cent. solution of Phenol before making the plates. While this method may enable one to eliminate many species of bacteria, Vincent himself acknowledges that *Bacillus coli* could not be eliminated by this process. Dunbar has clearly pointed out the fact that *Bacillus coli* is able to withstand a larger quantity of phenol than typhoid bacteria.

Several other methods of applying phenol to culture media have been suggested. The facts in hand, however, show that it is of little or no value in differentiating the typhoid and colon bacteria. By the judicious application of phenol, there appears to be no doubt that the discovery of typhoid bacteria is greatly facilitated. On subsequent plate cultivation the colonies will be limited to those of *Bacillus coli*, the typhoid bacillus, and possibly a few other forms. Any colonies at all resembling those of typhoid bacillus must then be further examined. For purely differential purposes, the character of the growth on gelatin, the production of gas when grown in a bouillon containing glucose in the fermentation tube, and by cultivating it in milk for the coagulation of the casein. The production of iodol is also a property of the colon bacteria not possesssed by the typhoid bacillus.

Care of the Teeth.

A dentist advises that acids are even worse than sweets upon the teeth and inveighs against the eating of oranges and apples at night without carefully rinsing the mouth afterward. Persons, too, with sensitive teeth, who dread the hour in a dentist's chair, will find their suffering somewhat relieved by being careful what is eaten before the appointment. Acids that set the teeth on edge are a poor preparation. The same authority recommends a small rubber band as the best toothpick. These are really better than the dental floss often advertised, or certainly quite as good, and much more apt to be at hand.—*New York Times*

ABSTRACTS.

THE ANIMAL PARASITES WHICH WE OBTAIN THROUGH OUR FOOD.

Dr. Wardell Stiles, Zöologist, Bureau of Animal Industry, U. S. Department of Agriculture, in a lecture before the Sanitary League of Washington, D. C., says:

As I am to show you some of the animal parasites which we may obtain from food, permit me to invite you all to lunch with me for half an hour or so, that you may see some of the wonderful objects it is possible for us to swallow without knowing it. The repast, to which I now invite you, is not such a one as you would yourself prepare, but it is one which might be prepared by the ignorant and slovenly servants of ladies who consider it a disgrace to know anything about household matters. For your comfort, however, I will tell you that a number of the parasites which I shall mention are not found in Washington, except as specimens in the various scientific collections,

The first course consists of soup—let it be any kind you wish, bouillon, mock-turtle or anything else. As we are about to take a spoonful we notice a curious object floating around in it, which upon closer inspection turns out to be a small beetle (*Blaps mucro nata*) closely related to our death-watch beetle. If we swallow this bug, the insect itself would not injure us in the slightest, for it would be digested, but according to the investigation of an Italian zoölogist, a little organism lives in this insect which, upon coming into our digestive tract and becoming free from the body of the bug, develops into the parasite known to the scientist as a thorn-headed worm (*Echinorhynchus moniliformis*). This is a curious worm about 2 to 4 inches long, with a strong proboscis on its anterior end, armed with several rows of hooks. Like many other parasites, it possesses no intestine, but, fastened with its head in the wall of our digestive tract, it floats in the contents and absorbs nourishment through its entire outer surface. For your comfort I will state that this is not a common parasite in man, but lives in rats. The rats scatter the eggs around, and these are swallowed by beetles, in which the larval form develops. When the insects are eaten by rats, or persons, the larval then develops into the adult and the life-cycle is thus completed. It may be interesting for you to know that when the Egyptian ladies wish to become stout, they are said to eat a beetle of this genus, and thus they lay themselves open to possible infection with these worms. Perhaps instead of finding a *Blaps* in our soup, we discover some other bug, say a small butterfly, by the name of *asopia farinalis*, or a beetle known to scientists as *akis spinosa*. In that case, instead of becoming infected with the thorn-headed worm, we should have caught a small tape worm (*Hymenolepis*).

You may think I have stretched a point by saying that these bugs may be found in soup, but I assure you that it is not an uncommon occurrence to find insects in soup, and that people swallow these insects, containing the germs of various parasites, is shown by the fact that the parasites I have mentioned occur in man and that the only way he could possibly catch them is by swallowing the insects I have referred to.

While our soup plates are being removed we unconsciously nibble at a piece of bread, at the same time that we are discussing the weather or some other equally exciting topic. Now let us suppose that this bread was cut by our cook—who, as I intimated, is not the most cleanly person in the world. The cook may herself be infected with pin-worms; she has unconsciously gotten some of the microscopic egg upon her hand, and in cutting the bread has unconsciously transferred them to the bread. They are too small for us to see, and in eating the bread, we accidently become infected with these germs. Pin-worms (*Oxyuris vermicularis*) are among the most common animal parasites found in human beings; probably fully one-fourth, possibly one-third, of the persons in this room have at some time during his or her lifetime harbored these creatures. If only a few worms were present, we were not troubled very much, but if many were present, we probably were quite unhappy for the time being, notwithstanding the enormous doses of soothing syrup or other mixture which our well-intending mothers gave us to keep us from being so restless during the night,

little suspecting what the real cause of our restlessness was.

These parasites are, as I have said, very common and may be obtained through solid food which has been handled by persons who are affected with them, and are not careful enough about washing their hands, or they may be obtained through unfiltered or unboiled drinking water, or through milk, when the milk-can, before leaving the farm, or even afterwards, has accidentally (?) stood for a few minutes too near a contaminated water supply.

If our servant has allowed the lid of our bread-box to stand open, and the mice have gotten in there, they have scattered on the bread microscopic parasites known to the zoölogist as *Megastoma intestinale*, and as we eat the bread we become infested with these germs also.

Our fish has now been served. Some of us have taken pike, others have taken turbot, still others have chosen some other fresh-water fish, but the essential point is that the fish has not been cooked enough. As we are eating this fish, one of us, who perhaps has sharper eyesight than the rest, discovers a white object, about one-fourth to one-half inch in length, which differs slightly from the muscle. This object upon closer inspection proves to be the germ or larval stage of the broad Russian tape-worm (*Bothricephalus latus*) which is the largest parasite found in man. The worm grows to be 32 feet in length. I spoke of it as a worm. In ordinary parlance we generally call a tape-worm a single animal, but scientifically speaking, the tape-worm is a colony of animals. The head, provided with two suckers, by means of which it holds fast to the wall of our intestinal tract, is what we have swallowed, as a germ or larva, with the fish, and represents the mother of the colony; while these segments, of which there may be hundreds, each represent individual worms of a second generation, the mother and all her daughters remaining joined together as a colony. It may be a satisfaction for you to know that this parasite is rare in America.

As our fish-plates are removed and we are waiting for the next course, consisting of meats, we introduce a new topic of conversation by taking a sip of unfiltered and unboiled water. It would have been better, perhaps, had we not taken that particular drink, for we have the risk of swallowing the germs of a number of different parasites.

We might, perhaps, have swallowed the eggs of the ordinary lumbricoid worm (*Ascaris lumbricoides*). This is one of the most common of the parasites found in the human species. I do not know how common it is in Washington, but I have records of examinations of 7,547 persons in certain European cities, and of this number 962 persons, or 12.7 per cent., or about one person in every eight, were infested with this worm, and there is no reason to suspect that the worm is any less frequent in this city. It is especially frequent among the school children, negroes and idiots, in fact among all classes of people who are not cleanly about their personal habits, and who drink unfiltered or unboiled water. In the city of Paris, where the entire water supply is filtered, the worm is exceedingly rare.

If we happened to be in Egypt, or in certain parts of Asia, we might have become infected with another worm, the guinea-worm by name (*Dracunculus medinensis*), which some scientists look upon as the fiery serpent of the children of Israel. This parasite, of which there is probably only one specimen in the United States, is about a yard long and lives under the skin; it produces large swellings, accompanied by an intense burning sensation, hence the name fiery serpent or fiery dragon, which it retains to the present day. The parasite is caught by swallowing small crustaceans in unfiltered drinking water, for the larval stage of this worm lives in these minute crabs, *Cyclops* by name.

Although we are not liable to catch the fiery serpent of the children of Israel in this part of the world, there is a somewhat similar parasite which we do stand in danger of catching. This worm, which scientists call a thread-worm (*Filaria sanguinis hominis*), lives in various parts of the body; the young embryos of the worms are found in the blood and are so small, about 1-1000 of an inch long, that a large number may be found in a single drop of blood. Now, when mosquitoes bite a person infected with these worms, the insects swallow a number of these microscopic germs along with the blood. The worms grow somewhat while in the body of the mosquito, and when Mrs. Mosquito, after spending four or five days digesting her meal, goes to some body of water to deposit

her eggs, the worms are ready for the next step in their life-history. After the mosquito dies and falls into the water, the young worms devour the internal organs of the insect, leave the mosquito and swim around until they are swallowed by the person who is careless enough to drink unfiltered or unboiled water.

In some other parts of the world another curious animal is caught from the water, an animal about half an inch long, which spends its earlier stages in a small crab, but which after being swallowed by man, lives in the large veins in his abdomen and causes a very serious disease.

But we have caught enough of parasites from that drink of water—let us pass on with our lunch. We have before us on the table a number of different kinds of meat. Some of us may prefer tongue, or roast beef; others may prefer pork of some kind, say roast pork, boiled ham, or if we are inclined towards German customs, we may take some duck stuffed with sausage. Let each one select his, or her own meat, and I will tell you what parasite you have swallowed, taking it for granted that all of the meats are underdone.

Those who have chosen beef in any form, as tongue, roast beef, smothered beef, steak, or stuffed veal, etc., have run the risk of catching the so-called beef-measle tape-worm (*Tænia Saginata*). This is the most common of the eight different species found in man. It is generally about fifteen to thirty feet long and is made up of a head and about 1,200 to 1,300 segments, each one of which you will recall represents a separate worm. These small bladder-like structures, about the size of a small bean, resemble bits of fat to a certain extent. These are the objects you swallow when you catch a beef-measle tape-worm. This cyst contains a tape-worm head bearing four suckers. When this is swallowed, segments begin to form very rapidly. In treating for tape-worm, it is always necessary to get rid of this head, for if that remains in the body the tape-worm will grow again.

Those of us who chose pork chops, roast pork, ham, or duck stuffed with pork sausage, have of course escaped the danger of becoming infested with the beef-measle tape-worm, but have run the risk of catching a smaller, but still more dangerous, tape-worm, *i. e.*, the pork-measle tape-worm (*Tænia solium*). The object we swallow in this case is almost identically the same as the object we would have swallowed had we eaten beef. The bladder-worm (*Cysticercus cellulosus*) lies in the muscle, surrounded by connective tissue, and as it comes into our stomach, the surrounding cyst is digested. The head and neck pass to a point in our digestive tract a little way below our stomach, and then begins the formation of segments, the segments always forming near the head, so that the last segment, that is, the segment furthest from the head, is the oldest, while the segment nearest the head is the youngest.

I said that this tape-worm is more dangerous than the beef tape-worm. Not because it causes us more pain while in the digestive tract, however, but because the microscopic embryos, which are formed in the segments, can under certain conditions bore through the intestinal wall and reach the inside of the eye or some other part of the body, and there develop into a bladder-worm. In this way, man, as well as hogs, may become infested with pork-measles.

But this is not the only parasite we have run the risk of catching in eating half-cooked pork. We may have eaten a piece of meat infested with the much dreaded trichinæ.

These trichinæ are curious little creatures, and although they are objects of considerable fear to the physician, who knows only too well that if these parasistes once gain access to a patient's muscles, he is utterly powerless to reach them and kill them with any medicine known, yet to the zoölogist these worms are of considerable interest.

They are very small, as you will believe when I state that as many as 350,000 may live in a single pound of meat. These minute worms live inside of the muscle-fibre of pork, coiled up like a spiral, with a small cyst around them. When we eat this pork, the meat upon coming into our stomach is digested and these minute cysts are liberated. The juices of our stomach then dissolve the cysts and Mr. and Mrs. Trichina pass down below our stomach and proceed to make life unpleasant for us. Mrs. Trichina becomes the mother of about 10,000 to 15,000 wriggling youngsters within a month's time, and these latter bore through our digestive wall and journey to the muscles. Upon arriving at some muscle which they find to let, they

into it and proceed to take possession of the contractile substance. The more of the contractile substance the trichinæ eat, the less there is for us to use in swallowing, breathing, walking, etc. After some weeks, however, the parasites have satisfied their appetite, and they become encysted, and our muscles present the same appearance which the pork had before we eat it. If our physician has succeeded in stimulating us up to the stage when the parasites become encysted, we will recover from the disease, and the trichinæ will do no further harm, until we go to Africa as missionaries, when the savages may suddenly discover that they have a bad case of trichinosis, should they not allow us to carry on our work unmolested. I should not, however, advise that we require candidates for the missionary field to first become infected with trichinæ in order to discipline the cannibals, but had our first delegation of missionaries passed through the disease of trichinosis before going to their fields of labor, the savages would by this time have learned that it was dangerous to use missionaries as an article of food.

I stated that we obtained our trichinæ from half-corked pork, but you may wonder how the hogs became infected. The matter is very simple indeed. These parasites are also found in rats, and as the hog is very fond of rats as a *delicatesse*, the hogs catch the parasites by eating rats. Rats keep up the infection among themselves by eating each other, for rats are cannibals.

We have, perhaps, not noticed that the odor of the meat brought our favorite dog into the dining-room. He is practically a member of the family and petted by all, none except the scientist looking upon him as anything except a most faithful friend, old Dog Tray! The scientist, however, is hard-hearted enough not to appreciate this friendship, and believing the proper place for a dog is the cellar, the barn-yard, the dissecting-room, or the dog-pound, he hygienically looks upon the dog as his enemy. Nevertheless, some of you do not share these opinions, and as the dog comes to you, you pet him and allow him to sniffle and lick your hand. But let us look for a moment at the animal parasites which the dog has given to you during that short caress!

Beloved old Dog Tray has in his nose a parasite about two to five inches long, a so-called tongue-worm (*Linguatula rhinaria*;) in sniffling and licking your hand he has deposited there some microscopic eggs, and the next time you take a piece of bread, you will transfer these eggs on the bread to your mouth. The eggs will be swallowed and the germ will bore from your digestive tract into your liver, and there develop into a parasite about one-quarter to one-half an inch long.

Or in caressing the dog, you have unconsciously gotten a flea or a louse upon your hands, perhaps under your finger-nails, and later you have swallowed that. It may now be a comforting thought for you to know that inside of that flea or louse, there lives the larval stage of a tape worm (*Dipylidium caninum*) with which you have become infected. But that is not all.

The most dangerous animal parasite which man has, is a so-called hydatid, which is the larval stage of a small tape-worm (*Tænia echinococcus*,) found in the dog. From the very nature of the habits of the dog we must not be surprised to find the eggs of this tape-worm upon his coat. Petting him, you get these eggs upon your hands; from your hands to your mouth is a short distance; you swallow the eggs and have become infected with the dreaded *Echinococcus*! The echinococcus develops in your liver, in your lungs, in your brain or elsewhere, and you suddenly discover the fact too late—perhaps it is not you who discovers it after all, but the physician who makes your post-mortem,—that the dog is your enemy rather than your friend. I am not now referring alone to the miserable collections of animated bones and dog-skins which wander into our city from Virginia and Maryland, but I refer to mamma's darling little poodle as well. In fact, from statistics it appears that this hydatid parasite to which I refer is most frequent among the dirty Icelanders who live in the same huts with their dogs, frequently sharing the same plate, and next in frequency in women who keep pet lap-dogs.

But our salad has come on the table. This salid—let it be any kind you prefer—was grown in a rather damp field; the year was perhaps an unusually damp year; and Bridget or Amanda is particularly lazy today and did not wash the salad as well as she would have done, had she expected that you would inspect the various courses

before they came on the table. Let us see what parasites we swallow this time.

First of all, we swallow a most remarkable animal, known as the common liver-fluke (*Fasciola hepatica,*) a parasite which is not particularly frequent in man, but one which is more common in sheep and cattle. A parasite which in 1830 killed more than 2,000,000 sheep in England, causing an estimated loss $20,000,000; and one which killed 1,000,000 sheep in Buenos Ayres in 1882; a parasite which kills hundreds of cattle and sheep in Texas every year, and has recently swept off nearly all the cattle on some of the Sandwich Islands. This parasite lays about 45,000 eggs, in each of which, under favorable conditions, a small ciliated embryo develops; this embryo swims around in the water until it finds a certain swamp-snail, into which it bores its way. Upon coming to rest (as a sporocyst) it produces a third generation (redia) which is however very unlike the first or second. This produces still another different generation (cercaria) which leaves the snail and encysts itself upon some plant, say, the kind used in our salad. When we swallow this cyst, the animal seeks out our liver and developing into the adult, proceeds to make trouble for us.

Nor is this the only fluke which we might catch in eating salad. A smaller one, the lancet-fluke of Germany (*Distoma lanceolatum*) or the Japanese liver-fluke (*D. sinense*) may be gotten in this way. The Chinese lung-fluke, which also lives in cats and tigers, and which Dr. Ward has recently found in this country, might make their homes with us, brought to us by improperly prepared food.

But I have introduced enough parasites to you to show you the necessity of preparing food carefully before it is placed upon the table. I hope I have not taken your appetites away for your meals tomorrow by making you disgusted with food, although I cannot say that I should feel very sorry if I had made you disgusted with pet dogs. Remember, that if your food is properly prepared, if your drinking water is boiled or filtered, and if you keep dogs from becoming too intimate friends with you, there is absolutely no danger of your catching any of these parasites that I have mentioned. But if you insist upon allowing your pet poodle the privilege of the dining-room, if you are careless about boiling or filtering your drinking water, and if you allow your careless servants to prepare your food as they wish, you in the meantime feeling it beneath you to enter the kitchen and see how matters are going on, you lay yourselves open to infection not only by these parasites of which I have spoken, but by many others.—*Diet and Hygiene Gaz.*

GENIUS AND DEGENERATION.

It is a strange fact, however, and one not noticed by Lombroso or any other writer, as far as I know, that mechanical geniuses, or those who, for the most part, deal with materal fact, do not, as a rule, show any signs of degeneration. I have only to instance Darwin, Galileo, Edison Watts, Rumsey, Howe and Morse to prove the truth of this assertion. It is only the genius of æstheticism, the genius of emotions, that is generally accompanied by unmistakable signs of degeneration. Swinburne's poems show clearly the mental bias of their author, who is described as being peculiar and eccentric. Many of the men of genius who have assisted in making the history of the world have been the victims of epilepsy. Julius Cæsar, military leader statesman, politician and author, was an eplieptic. Twice, on the field of battle, he was stricken down by this disorder. On one occasion, while seated at the tribune, he was unable to rise when the senators, consuls and prætors paid him a visit of ceremony and honor. They were offended at his seeming lack of respect, and retired showing signs of anger. Cæsar returned home, stripped off his clothes and offered his throat to be cut by any one. He then explained his conduct to the senate, saying that he was the victim of a malady which, at times, rendered him incapable of standing.

Many men of genius have suffered from pasmodic and choreic movements, notably Lenau Montesquieu, Buffon, Dr. Johnson, Santeuil, Crebillon, Lombardini, Thomas Campbell, Carducci, Napole-

and Socrates. Suicide, essentially a symptom of mental disorder, has hurried many a man of genius out into the unknown. The list begins with such eminent men as Zeno, Cleanthes, Dionysius, Lucan and Stilpo, and contains the names of such immortals as Chatterton, Blount, Haydon, Clive and David. Alcoholism and morphinism, or an uncontrollable desire for alcohol or opium in some form or other, are now recognized as evidences of degeneration. Men of genius, both in the Old World and in the New, have shown this form of degeneration. Among the men and women of genius of the Old World, who abused the use of alcohol and opium, were Coleridge, James Thomson, Carew, Sheridan, Steele, Addison, Hoffman, Charles Lamb, Madame de Staël, Burns Savage, Alfred de Musset, Kleist, Caracci, Jan Steen, Morland Turner (the painter), Gerard de Nerval, Hartley Coleridge, Dussek, Handel, Glück, Praga, Rovani and the poet Somerville. This list is by no means complete, as the well-informed reader may see at a glance, yet it serves to show, however, how very often this form of degeneration makes its appearance in men of genius. In men of genius the moral sense is sometimes obtunded, if not altogether absent. Sallust, Seneca and Bacon were suspected felons. Rousseau, Byron, Foscolo and Caresa were grossly immoral, while Casanova, the gifted mathematician, was a common swindler. Murat, Rousseau, Wagner, Clement, Diderot and Praga were sexual perverts. Genius, like insanity, lives in a world of its own, hence we find few, if any, evidences of human affection in men of genius.

Dr. Johnson, who was a sufferer from *folie du doute*, had to touch every post he passed. If he missed one he had to retrace his steps and touch it. Again, if he started out of a door on the wrong foot, he would return and make another attempt, starting out on the foot which he considered the carrect one to use. Napoleon counted and added up the rows of windows in every street through which he passed. A celebrated statesman, who is a personal friend of the wirter, can never bear to place his feet on a crack in the pavement or floor. When walking, he will carefully step over and beyond all cracks or crevices. This idiosyncrasy annoys him greatly, but the impulse is imperative, and he cannot resist it. Those who have been intimately associated with men of genius have noticed that they are very frequently amnesic or "absent-minded." Newton once tried to stuff his niece's finger into the bowl of his pipe, and Rovelle would lecture on some subject for hours at a time, and then conclude by saying "But this is one of my arcana which I tell to no one." One of his students would then whisper what he and just said into his ear, and Rovelle would believe that his pupil "had discovered the arcanum by his own sagacity, and would beg him not to divulge what he himself had just told to two hundred persons."

We must not confound genius and talent—the two are widely different. Genius is essentially original and spontaneous, while talent is to some extent acquired. Genius is an abnormality, but one for which the world should be devoutly grateful. Psychos, in the case of genius, is not uniformly developed, one part, being more favored then the others, absorbs and uses more then its share of that element, whatsoever it be, which goes to make up intellectuality, hence the less favored or less acquisitive parts show degeneration. Why genius should exist is one of the unexplained phenomena of nature, but that it is the result of natural causes I have not the slightest doubt.—*Med. Rec.*

Etherization of Incarcerated Hernias.

Since 1891 Gussenbauer has successfully made use of Finklestein's method of treating incarcerated hernia. This consists in dropping ether (one to two tablespoonfuls every quarter of an hour) upon the hernia ring and the tumor, the skin over these places having been previously anointed with vaseline to prevent irritation from the ether. This is employed from one to three hours in connection with elevation of the pelvis and gentle taxis. Among 135 cases treated during this period this treatment was indicated in but 31; in the others, owing to the long duration of the strangulation and the violent symptoms (marked tympanites, impending or developing gangrene), herniotomy was resorted to. Of these 31 cases 25 were treated by the ether method, the remainder by simple pelvic elevation and application of ice. The application of ether was successful in 20 cases (16 inguinal, 1 parumbilical, and 3 crural hernias), while in five cases it was necessary to subsequently perform herniotomy.

SOCIETY REPORTS.

OBSTETRICAL SOCIETY OF CINCINNATI.

Dr. Edwin Ricketts read a paper on

EARLY DIAGNOSIS OF CANCER OF THE UTERUS.

(See page 285.)

DISCUSSION.

DR. A. W. JOHNSTONE: This is a most important subject, and I know every one of you are sitting here thinking of cases. I was thinking of a case that I saw years ago, before such a thing as extirpation of the uterus was ever thought of; had we known then what we know now the life of that patient would probably have been prolonged, but I doubt whether it would have been saved. I speak of it to illustrate the rapidity of growth. I saw the case in 1884. The patient was large and fleshy, and had no constitutional symptoms of any description, but had a pain about the uterus. I found what I thought was a little fibroid of the uterus. In less than a week I saw her again; she had a little hemorrhage, and sticking in the mouth of the uterus was a little polypus. Microscopical examination showed it to be cancerous. In less than three weeks it had filled the cavity. It was a simple ordinary carcinoma. The thing to do in carcinoma is to remove it as clean as you can. However, it is so insidious that sometimes before it breaks down or there is any smell the case is gone, and you will find it involving the lymphatics and almost in a hopeless condition. If the patient is a little stupid and pays no attention to herself, the slight symptoms may be overlooked and you will not be called until it is too late. That has been my experience, and I suppose always will be the experience of all of us.

Some of you know my ideas about carcinoma. It has been a fad of mine for some time, and my ideas have crystalized down to the view that it is due more to the failure of the trophic nerves than to anything else. You know they are totally different from the adult tissue, and it is a trite saying that carcinoma is simply a return to the fetal state. Years ago I studied this in the lymph glands, and it is really beautiful to see that the transformation of them is very similar to the process of bone. After studying it all over I have come to the conclusion that it must be some failure of the trophic nerves. I remember about a year ago, while walking home from the Academy with Dr. Conner, after a discussion in which there had been nothing said as to the cause, I suggested this idea to him, and he said: "Yes, and you will see more than that if you study your cases closely. You never saw a case of cancer in your life that was not preceded by some nervous strain This is frequently the death of a husband or child, or financial reverses." And he quoted Grant's case as an example, where he had climbed to the highest pinnacle in the United States, and his son had wrecked him, and he said: "That is a typical case of cancer, and you will always find them preceded by some terrific nervous strain." So I believe that carcinoma is due—and sarcoma to a certain extent, too—to a failure of the trophic nerves; that this storage-battery is exhausted in old people, so we do not have the central control. The cancer is found in the remnants of the fetal structure; in the ovary it usually occurs in hilum, which is really the remnant of the second set of kidneys, which should have shrunken up and been only scar tissue. However, there is carcinoma is likely to appear. In the uterus, it is in the cervix, just after the uterus passes out of its usefulness. The same way with the breast, where it is most likely to occur at the menopause.

There is another thing you may urge against the etiology of carcinoma. I remember years ago, as a boy, one thing I read in either the London *Lancet* or *British Medical Journal*, that gave a clue to the development of carinoma. Some surgeon of the British Army in the foothills of the Himalayas, came in contact with the Hindoos. In their clothes they have a foolish habit of carrying a little bit of charcoal, and when cold they just squat down on it so as to bring it against the thighs or chest. In this way scars are produced, and he gave a list of two or three hundred carcinomas comming out of these scars on the thighs and chest,

localities where we never hear of it in other parts of the globe. The scars are kept irritated constantly by the charcoal being carried under the clothes and giving off fumes and irritative gases.

I believe in every part of our body we have a nerve coming from the trophic centre, whether this is the stomach or the cerebro-spinal system, which keeps the tissues of the body regulated. With that cut off, the tissues are apt to do their own sweet will, and the tendency is to go back to the fetal state. I believe we are a great republic, with a great central control, and every nerve in the body has to have a certain control. When this is cut off, the cells go back to the original state. You may say this is all theory and of no practical good, and you cannot convert it into dollars. I believe you can; it is not time yet.

I have one case which I have followed carefully and thoroughly. I do not feel I should as yet make a report of it, but I will tell you what I have seen. There is no mistake about it being a cancer; it came to me with a terrific ulceration, and was so diagnosed by two men in New York City. I opened the abdomen to take it out, but found a big chunk of a cancer involving the right ureter; I closed it up and quit. I then went to work to increase her nerve force if possible, and at the same time cleansed the vagina daily with the peroxide of hydrogen. Whether it was the disinfection or the manifest improvement of the woman's condition, I do not know, but that ulcer healed and skin grew over it. But the nodule continued growing. I have been working on the case over a year, and the gentleman from New York, whom I had previously seen, said he thought she would be under the sod long ago. The cancer has not been arrested, except to the extent that the frightful itching and the boils she had about the labia have all ceased; the growth of the cancer has not been arrested, but the ulceration was arrested.

This is a line along which I have been working for some time, and I hope some day we will have something; I beg of all of you to go to work along that line, restoring the nerve-force of the patients, so that if we get them up we can keep them from coming back. I remember my old professor saying that the day is coming when we will cure cancers with the hypodermic syringe, and I must say there may be something in it.

I can only congratulate the essayist upon the paper of the evening, and it will be my intention to follow his instructions as far as possible, and take them out as soon as possible. Some I have cut out, and now after ten or twelve years they have not returned. The longest case of cancer I know of was in a very young fellow, a medical friend of mine, two years younger than I am. He had yellow fever, and in the delirium bit his tongue. He was an interne in the Charity Hospital of New Orleans. He had Bright's disease afterward, and this sore place he afterward went to doctoring, and a nasty granular tissue sprung up. It was cut out and examined, and he was told it was cancer. He came home, but was still kept down with the Bright's disease. He granular tissue sprung up. It was cut out and examined, and he was told it was cancer. He came home, but was still kept down with the Bright's disease. He dragged on for six months or a year, and this thing sprang up again. I cut out a funnel-shaped piece all around it and sent it to a doctor in New York, and he said there was no doubt but it was cancer. He then weighed about 130 pounds, and now will weigh about 230. Most of the cases I have treated thus have done about that way. I believe if we ever get carcinoma under control it will be principally through the nervous system.

DR. PALMER: I believe every member here is obliged for the elucidation, theory and facts given us by Dr. Johnstone. The theory is very plausible; there is undoubtedly considerable fact in it. What is true in the case of General Grant is probably true in many other cases. The nervous condition has much to do with producing cancer. One of the most potent agents we have to control cancer is arsenic; the Fowler's solution is probably the best remedy we possess for the treatment. It has its influence upon the nervous system, and will control the cancer better than any other remedy we can give. It is also a potent, but not safe, remedy to apply topically.

While the paper was being read by Dr. Ricketts there occurred to my mind a means of diagnosis, mentioned years ago, which I think is of value. I am not disposed to discount anything he has

said as to the value of the special senses, sight, taste, touch and smell, or the use of the microscope, which is probably the best of all. But a gentleman in Germany a good many years ago spoke of the reliability of the dilatation produced by the sponge in the diagnosis between hyperlastic induration and the induration from a cancerous growth. The former will yield eventually and be dilated, whereas the latter will not yield, and will remain while the parts around dilate. However, I believe the microscope is the best means we have to determine cancer, and should be used in every case of doubt.

DR. A. B. ISHAM: I came down to-night to listen to the practical paper which has been read upon the early diagnosis of cancer, and not to offer any remarks; but since you were so kind as to call upon me, I may say that we cannot diagnose cancer upon the discharges, or the smell, or the induration of the cervix, because we may have all these conditions from specific disease of the cervix, and of the body of the uterus. There occur to me now three cases in which there was the most offensive smell it is posssble to conceive of, and which in this particular were equal to any cases of cancer I have ever met with, where there was a thickened condition of the cervix from tears due to parturition, where all the varied forms of the discharges met with in cancer were present, and where there was no positive evidence of specific trouble, but simply a suspicion. They were all cured by specific medication.

I think Dr. Johnstone's remarks, in reference to cancer being due to a disturbance of the trophic nerves, are directly to the point, for carcinoma is nothing more than cell proliferation, and where there is an affection of the trophic nerves cell nutrition may run riot. Perhaps we may sometimes find a remedy to control nerve action among the glandular extracts.

In conclusion, I wish to make an inquiry suggested by the paper, and that is whether there is a specific cancer cell, a cell that microscopically admits of no doubt of its being carcinomatous in its nature.

DR. RUFUS B. HALL: I did not expect to speak on this subject. If the theory of our friend Dr. Johnstone is true, how do we account for the large number of cases coming under observation with cancer in various parts of the body, in which the patient has no indication of any marked nervous derangement in any way?. I am not questioning the truth of the theory, but ask this for information. I am not giving special study to this subject, as he is, but while listening to his interesting remarks I can recall many cases of cancer of the uterus and cancer of the breast in which the patient was otherwise in apparent health. And then, again he recited the fact that this followed so frequently after nervous strain or some great mental stress or misfortune. I think the large majority of cases of cancer coming under my observation have occurred in patients without unusual mental strain, anxiety or worry. I do not believe the majority of cases are found in patients who have passed through such anxiety or strain as would make that a factor in the prodnction of disease. I congratulate Dr. Johnstone upon his theory, and hope he will work out a problem that will be of value to us all, but the fact that we occasionally see cancer in these patient I do not think is sufficient to enable us to make that a factor in the diagnosis of cancer. We occasionally do see cancer in these patients. Where the disease is far advanced, we see the patients suffering with nervous manifestations, but do we see it early in the disease so marked as to make it a factor in the production of the disease itself? I don't want to say this in the spirit of criticism, but as a matter of fact coming under my observation, and I would like to ask Dr. Johnstone if he has any explanation why this is so.

DR. JOHNSTONE: The reason is Dr. Hall has not studied his case close enough. What I mean is mental anxiety and worry, and not brain trouble or any manifestation of hysterics, but something that is giving the mind all it can possibly stand. When Dr. Conner first sprung this idea upon me I was like Dr. Hall, and did not think there was much in it. Since then, however, I have not let one of these cases go away from me without a careful questioning, and every one of them have a skeleton. This is true in nearly all of these cases. Now, I did not expect to speak of this, but expected to write a paper on it. While this may not be the correct line, it may lead us on to find something of practical value. Since Dr. Con-

ner called my attention to the universal worry of these people, and he spoke of it as a general surgeon, I have made a practice of winning the confidence of these patients, and in every case I have found a skeleton in the closet worrying the soul out of them.

But there is another thing and that is heredity. How many of these people may inherit this tendency? It was the old idea that cancer was as hereditary as consumption. The heredity of consumption now is found to be only a weakening, by which we cannot fight the bacilli. Some people may stand worry better than others, and others may be comparatively weak. But then on top of it all we may find something else. At one time we thought there was only one Bright's disease; we may yet find that there are a dozen different kinds of cancer. The nerve idea certainly deserves close study. Certainly those fellows in the Himalaya Mountains cannot have much worry, but in those cases there is enough constant irritation to produce it. But you think of an old psoriasis, which goes on year after year, and you would think if anything would kill out the nerve centre it would be that. These cases develop *de novo* almost.

The doctor was asking the present condition of cancer, and what we know about it microscopically. In 1888 I published a paper on the growth of the cancer in the lymphatic cells, which bears directly upon this question. The round cells simply melt together, just as they melt in the formation of bone. You know Miller's idea—but it is too long to give you—regarding the calcification and decalcification, and the laying down of the Haversian system, etc. The round cells, I think, spring from the connective tissues, and wander around and in turn run into the Haversian system. Until then you do not have the complete formation of the cancer nest. The round cells have frequently gone on ahead. They are the robbers that set up the rebellion; they have gotten out in the connective tissue spaces, and there you find it beginning. It is not the cancer but it is this round cell we must get rid of. The key is to get ahead of that round celled invasion, for that is what makes the cancer grow. The nest is as the ashes after the fire has passed.

Dr. Hall: I want to discuss the discussion and not the paper. I still disagree with Dr. Johnstone. For every case of that kind coming under my observation, in which there was a well-marked predisposing cause, at least a half-dozen cases have been under my observation in which there was no such cause. I do not agree with the doctor, but do not oppose the theory.

I want to emphasize one point in Dr. Rickett's paper, and that is the fact that these cases are referred to the operator so often for operation or diagnosis when the patient is beyond any operation—that is, the disease has passed so far that any operation is out of the question. In my paper before the American Association of Obstetricians and Gynecologists last year upon this subject I referred to that point. For each operable case sent in by physicians there are about ten who are past any operation. That has been about the ratio ever since that paper was written. Nearly all the cases have been under observation for months, but the physician in charge, not feeling certain as to the nature of the case, is afraid of making a blunder. Now, that ought to be righted in some way, and ought to be righted by the members of this society. Let the family physicians know that we are not going to criticise them if they refer to us a suspected case of cancer. They are afraid they will be criticised, and it will affect their reputation. Although I am of course, free to say no man would do that, yet it is done.

Dr. Chas. Bonifield: I remember reading in the London *Lancet* or the *British Medical Journal*, a lecture in which this was spoken of, but a fatal objection to it in my mind is that it is not particularly in nervous people we see cancers. If that were the cause, it seemes to me it would be in these slight, nervous women that we would most often find it, but we more frequently find it in the fleshy, phlegmatic people. If you come to put down care, and trouble as the cause for the diseasee you can find it for almost every disease we have to treat. It has been very frequently brought forward as a cause for Bright's disease, and has always seemed to me more truly a cause for that than for cancer. There are very few people but have a skeleton in the closet, and if we question them close enough we will find either a little one or a big one.

Dr. RICKETTS: It seems things go in spurts, even surgery, and at present I have no less than fifteen or twenty cases of cancer under observation, and in the last few days it seems to me every case I have examined has been cancer.

Now, while I hope the time will come when we will have made known to us the true cause of cancer, yet while they are hunting for that cause I propose to be one of the number to advocate the earliest possible diagnosis of cancer of the uterus, on common-sense principles, and urge the earliest possible extirpation of that cancerous nodule. While we have our friends who are ready to theorize, and I will admit they are working on lines that are commendable, yet I have been asked even lately by physicians, "will you tell us how we are to get hold these cases earlier, and when we get hold of them how we are to know they are to be operated upon?" Dr. Johnstone spoke of the women knowing about it. All women cannot be made to diagnose these, and the general practitioners cannot be expected to carry microscopes around in their saddle-bags. As I stated, there are three things given to man that do not cost him much and yet I think they have been overlooked to a great extent; in other words, the cart has been put before the horse, and I feel justified in saying that these cases must be gotten at earlier. In this house to-night there is a patient in whom I propose to extirpate the uterus for prolongation of life and a palliative measure, and for nothing else. The patient is begging for comfort.

In regard to the theory of Dr. Johnstone, I call to mind quite a number of cases of cancer, and while I can recall a number of them who are very nervous subjects, yet I can call up a number of cases in as jolly subjects as I know of, and in which I have been unable to unearth anything to indicate that they had suffered from any depression of any kind. I look at it in this way, that we must get at these women in some way; I do not care whether it comes through the microscope or what, but get them so they will promptly consult their physicians when they have this leucorrhœal discharge followed by the watery discharge, which may be productive of a bad odor, and then I believe we will have made a step in the treatment of cancer such as we have never made heretofore.

The Value of Sugar and the Effect of Smoking on Muscular Work.

As the result of a series of experimental researches in the Physiological Institute, Turin, as to the value of sugar and the effect of smoking on muscular work, Vaughan Harley (*Journ. of Phys.*) has come to the following conclusions: (1) The periods of digestion as well as the kinds of food taken have a marked influence on voluntary muscular energy. (2) Irrespective of the influence of food, there is a periodical diurnal rise and fall in the power of performing muscular work. (3) More work can be done after than before midday. (4) The minimum amount of muscular power is in the morning about 9 A. M., the maximum about 3 in the afternoon. (5) Regular muscular exercise not only increases the size and power of the muscles, but has the effect of markedly delaying the approach of fatigue. (6) The amount of work performed on a diet of sugar alone is almost equal to that obtained on a full diet, fatigue, however, setting in sooner. (7) In fasting, large quantities of sugar (500 g.) can increase the power of doing muscular work during 30 voluntary contractions from 26 to 33 per cent., while the total gain in a day's work may be 61 to 76 per cent., the time before fatigue sets in being also lengthened. (8) The effect of sugar is so great that, when added to a small meal, it can increase the muscular power during 30 contractions from 9 to 12 per cent., while the total increase in work may be from 6 to 39 per cent., the approach of fatigue being at the same time retarded. (9) When added to a large mixed meal, sugar can increase the muscular power of 30 contractions of 2 to 7 per cent., the increase in total work being 8 to 16 per cent., and a marked increase in the resistance to fatigue is shown. (10) Two hundred and fifty grammes of sugar taken in addition to a full diet increases the day's work; the work accomplished during 30 voluntary muscular contractions shows a gain of from 6 to 28 per cent., the total day's work giving an increase of power 9 to 36 per cent., and the time before fatigue sets in being lengthened. (11) Moderate smoking, although it may have a slight influence in diminishing the power of doing voluntary muscular work, neither stops the morning rise nor, when done early in the evening, hinders the evening fall.

CURRENT LITERATURE REVIEWED.

IN CHARGE OF ELLISTON J. MORRIS, M. D., AND SAMUEL M. WILSON, M. D.

IN THE BRITISH MEDICAL JOURNAL

of July 28, 1894, are some

Critical Remarks on Sir Andrew Clark's "Theory and Treatment of Renal Inadequacy,"

by Sir George Johnston, M. D.

The author here tries to show that the condition declared due to an underaching, but seemingly otherwise normal, kidney, is not due primarily to the kidney. There is here a deficiency of solids in the urine, but it appears due to deficient formation of solid urinary constituents, and not to their formation and retention in the blood. In support of this, the statement is made that the slow, powerful heart beat and tense pulse do not occur, as they do when excreta are retained in the blood. The symptoms are credited to deficient oxidation and imperfect digestion, and the author thinks they are best relieved by a combination of vegetable bitters, with or without pepsin and hydrochloric acid. The lessening of the diet is, of course, very important, but it probably acts by allowing a weak stomach to properly dispose of a small amount of food, rather than by offering to the kidneys an amount of urea, etc., so small that they can excrete it.

Dr. Lloyd G. Smith reports

Five Cases of Hydrocele in the Female.

This affection he says is less uncommon than is generally supposed; is frequently painful, but may be unnoticed until an accident calls the attention to it, and is generally mistaken for hernia. The author thinks the only means of differentiating this from hernia is by making traction and tracing the neck of the sac, which will be found smaller than that of a hernia. This is not possible in all cases, of course, and as there is generally pain connected with the tumor; when seen, the author prefers to operate. He makes a linear incision, ties the neck of the sac, shells it out and sews up the wound, usually getting primary union.

Dr. George F. Hill reports a successful case of

Treatment of Diphtheria by Antitoxin.

The patient was three years old, admitted at 2 P. M. with croupy cough and difficult inspiration. The tonsils were somewhat injected and swollen and with a patch of membrane on the right one. Temperature was 102 4°, pulse 140, respiration 32. At 4:30 P.M. an injection of eleven minims of antitoxin (Sherring's) was given, and at 6 P.M. the temperature was 99.2° with some general improvement. The next day, as the child was becoming restless again, eight minims were given at 4:30 P. M., and on the following day the temperature was normal, the symptoms abating, and the child playing, talking, and using solid food. The croupiness persisted until the fourth, and the membrane until the seventh day. The diagnosis was confirmed by cultivations from the membrane. In addition to the injections a thirty minim dose of brandy was given every four hours, a spray of iodine and carbolic acid used twice on the day of admission, and a tent bed with steam used as usual.

Other papers in this issue are "On Death Rates," by Dr. G. H. Fosbroke; "The Personal Factor in Disease," by Dr. Leonard W. Sedgwick; "The Modern Development of the Germ Theory," by Dr. Henry Langley Browne; "The Cycle of Life," by Dr. J. Sidney Turner; "Medical Organization and Remuneration," by Dr. J. McCarthy; "The Spirit of Quackery," by Dr. J. West Walker.

THE AMERICAN JOURNAL OF OBSTETRICS

for July contains an article by Dr. William M. Polk on

The Conservative Surgery of the Female Pelvic Organs,

in which he discusses principally the three conservatisms of the latest date—myomectomy and ligation of the arteries of the uterus in fibroids; curettage and "tamponade" in all forms of endometritis, whether acute or chronic, puerperal or non-puerperal. In regard to myomectomy he enumerates the indications for the operation as follows, naming the conditions in the order of efficiency:

1. It is applicable to uteri which possess only pedunculated tumors.
2. To uteri whose tumors possess well-developed fibrous capsules, and which are neither so large, so numerous, nor so placed as to require in removal such direct damage to the uterus or to its blood supply as will unfit the organ for proper fuuctional activity.

Of the ligation of the broad ligaments of the uterus to check the growth of fibroid disease he says: "The fact that it aims to accomplish a beneficient purpose without the dangers of a more extended operation, and that it appears to fulfill its purpose as well or better than is done by oophorectomy, commends it to us in cases unfitted for myomectomy on the one hand or incapable of withstanding the radical operation on the other. Our knowledge is insufficient at present to permit us to go beyond this statement."

The author is a firm believer in the efficacy of curettage and gauze packing in all forms of endometritis and metritis, whether acute or chronic. "The most striking results are those obtained in the face of the acute septic inflamations of the organ which occur after abortions or labors; but to be of proper service the measure should be properly applied, delay affording opportunity for systemic infection, after which the treatment, though far from useless or dangerous, is of less service." He urges that at the first sign of an outbreak of sepsis following labor or abortion, the physician should forgo his vaginal douches and other expectant measures and boldly enter the uterus and curette and pack with aseptic

gauze. He contends also that the measure is also of great service in the chronic inflammations and states that "whenever in chronic inflammations the uterus is yet enlarged, is yet in the stage of infiltration, this measure is applicable. This brings within its influence many of the so-called cases of recurrent salpingitis and every case where endometritis, and particularly metritis, persists." As to the resection of ovaries that are the seat of simple or blood cysts, he states that in practice one meets with two classes of simple cysts—in one we have one, two, or at most three, cysts, varying in size from that of the ordinary corpora lutea to a dimension several times as great. In the other class we have many small cysts scattered indiscriminately throughout the cortex of the organ. In dealing with the first class of cases and with hematoma he contents himself with free enucleation, bringing the cut edges together with catgut or silk. In the second class of cases he resorts to ignipuncture of all cysts that can be reached, even laying open the ovary by one free incision to get access to cysts buried in the parenchyma.

The author closes his paper with a word on the subject of tubes whose canal is intact and whose ostium abdominale being open, presumably both are. Presupposing that the ovary or a part of it can be left, his rule has been to free such tubes from imprisonment and leave them, treating the associated endometritis by tamponade. When the tube presents itself with closed or partly closed ostium abdominale, and containing but little muco-purulent secretion, the conditions indicating that the closure is of recent date, he opens such tubes at the ostium, cleanses them, and after stitching back the fimbriated rim, thus giving a free opening, leaves them. When the tubes have seemed fit for preservation the adhesions have not been permitted to contraindicate conservatism.

Dr. W. Gill Wylie contributes a paper on

The Best Method of Operating on Old Lacerations of the Perineum, Especially Those Associated with the Formation of a Rectocele and Displacement of the Uterus.

Regarding the perineum as a movable point of attachment for the transversus perinei, the bulbo-cavernosus, the sphincter ani, levator ani, and some of the pelvic fasciæ, and also as the movable point of attachment for the anus and lower end of the rectum and the lower end of the posterior wall of the vagina, the conclusions are:

1. As a rule, when the perineum is completely severed so that the fecal matter escapes passively, the position of the uterus is not affected.

2. The outer or lower part of the perineum may be torn to a considerable extent and the position of the uterus will not be affected.

3. When the inner or upper part of the perineum is torn or overstretched and relaxed, prolapse of the posterior and anterior vaginal walls will take place, and in time the uterus is retroverted, prolapsed, and may be forced out of the pelvis.

4. The explanation is that when that part of the perineum formed by the fibres of the levator ani and the pelvic fascia where they encircle and are attached to the lower end of the vagina or anus, is torn apart, the lower end of the vagina and the upper part of the anus are loosened so that they are not held up and elevated when intra abdominal force is exerted, as in straining at stool; both are forced out through the vaginal outlet, and they pull and drag down the uterus, and in time may result in hernia of the pelvic organ.

5. In operating to restore the parts we should aim to reunite the separated edges of the levator ani and the pelvic fascia, and fix them to and in front of the lower end of the rectum and the upper part of the anus, and thus prevent the fecal matter from forcing forward the anterior wall of the rectum and putting on the stretch the posterior wall of the vagina and in this way displacing the uterus downward and throwing the fundus backward between the utero sacral ligaments, etc.

6. This can be done efficiently only by denuding the retracted tissues on either side of the rectocele and uniting them over and in front of the rectocele. As the most important laceration is within the ostium vagina, to reach these tissues the operation must be within the vagina; and to secure good apposition and to avoid dragging down and adding to the tension, most of the sutures should be passed within the vagina from side to side, so as to unite the edges of the pubo-coccygeus muscle and pelvic fascia in front and over the upper end of the anus and the lower end of the rectum, in such a way as to deflect the fecal matter, as it descends to the lower end of the rectum, back through the anus, and thus effectually prevent the formation of the rectocele with its results on the vagina and the uterus.

7. As a rule, when in an old laceration there is a rectocele with retroversion, etc., there will be found an abnormal condition of the anus and lower end of the rectum. There are nearly always hemorrhoids, fissures, or erosions of the anus or rectum, and not infrequently the sphincter ani is abnormally developed, contracted, and irritable, and on this account it is often necessary to remove these conditions to effect a cure of the case. And it is always best to freely dilate the rectum before sewing up the lacerated vagina.

8. Even where there is complete procidentis, with the cervix or whole uterus out of the vaginal opening, this operation can be made to effect a permanent cure in most cases by combining with it amputation of the cervix uteri, and inserting the sutures so as to shorten up the portion of the stump left in the vagina and, as it were, tie up the upper end of the vagina to the upper part of the cervix uteri at the os internum; or, in those cases where there is retroversion, by doing Alexander's operation to shorten the round ligaments, and thus prevent the long axis of the uterus becoming parallel with the axis of the inferior strait of the pelvis and acting as a wedge to be pushed out, by every effort at stool, through the mouth of the vagina and reproducing the procidentis.

Excluding cases of enlargement from in-

tractable and incurable disease or new growths, the author does not believe in removing the uterus on account of extreme prolapse or procidentia, for, with rare exceptions, they can be cured by the above operations.

The paper is illustrated with cuts, showing the author's method of denudation.

Dr. J. M. Baldy, in an article on

Extirpation of the Uterus in Disease of the Adnexa,

says that " where the womb itself is greatly enlarged, infiltrated, or diseased, it is a proper subject for removal.

Where there is any good reason for believing that this organ will in future become the seat of disease, it may with propriety be extirpated. Where its removal will facilitate an operation or give greater security against hemorrhage, it is justifiable to extirpate the organ.

Except in the presence of malignant or tubercular disease, the womb should never be disturbed if even a portion of one ovary and a Fallopian tube can be preserved. Nor is an operation to be extended to the performance of hysterectomy, where the double ovariotomy will even temporarily answer the purpose, should the patient be in such condition that the prolonged manipulation might render the result of a given case doubtful."

The author advocates the removal of the uterus in disease of the adnexa on account of the number of cases in which the removal of the diseased appendages has not given the relief sought and in which the subsequent removal of the uterus was necessary. He contends that the uterus without the adnexa is not essential or useful. He prefers the abdominal operation to the vaginal.

This issue contains two papers on Rupture of the Uterus. The first by Dr. Charles M. Green, is entitled:

Rupture of the Uterus; Palliative Versus Surgical Treatment.

The author reports two cases treated by palliative measures, both of which recovered. He also presents tabular statements of cases treated by various methods, surgical and palliative. His conclusions are that for purposes of treatment we may divide cases of uterine rupture into three classes :

1. Complete or incomplete tears of the lateral or posterior walls of the lower segment, with adequate provision for the vaginal drainage, with hemorrhage absent or easily controlled, and with no intestinal hernia; such cases will often do well under simple palliation, with natural vaginal drainage, local antisepsis, general supportive treatment, and measures to promote and maintain firm contraction of the uterus.

2. Complete tears of the lower segment, or even moderate tears of the uterine body, with hemorrhage controllable *per vaginam* with gauze pressure or partial suture, where the child has passed through the rent, and where more or less blood clot and liquor amnii, and perhaps also the placenta, have entered the peritoneal cavity ; for this class of cases peritoneal irrigation with weak antiseptics or sterilized salt solution, drainage with iodoform wicking or gauze, combined with general palliative measures, would seem most appropriate.

3. Cases in which delivery of the child through the pelvis is impossible or inexpedient ; in which there is present hemorrhage uncontrollable *per vaginam*; in which the rents in the uterus are extensive, and of irregular, transverse, or ragged character ; for such cases abdominal section is indicated. The propriety of suturing the rents must be decided according to the condition of the uterus and the edges of the tears; when the latter are very ragged and infiltrated with blood, when the uterus is friable and apparently septic, hysterectomy promises better results than suture.

The second paper is by Dr. Malcolm McLean, and is entitled

The Palliative Treatment of Rupture of the Uterus.

The author is of the opinion that instrumental delivery of the child should not be resorted to, but that it should be turned and delivered by the hand alone. He gives as his reason for so advising, that the recession of the head makes the operation with the forceps a very uncertain and dangerous one, the flaccid uterine tissue being easily caught in the instruments and a satisfactory grasp of the head being almost impossible. And when version is resorted to, after an ineffectual and probably disastrous attempt to deliver by the forceps, it becomes a much more grave operation by reason of these previous attempts. If version be performed promptly, and with the hand kept well in contact with the child and not impinging against the uterus, he maintains that it is a safe operation compared with any attempt at delivery with the forceps within the uterus. While the child is quickly yet gently extracted the placenta with its membranes may be readily detached and the whole sac drawn away with its contents which will leave a clear uterine cavity with an uninfected wound of its tissues, which may be left to nature's processes of repair. While the hand is in the uterus it should rapidly, yet with great care, be swept freely along that part of the child which is engaged in, or impacted against, the wound in the uterine wall. The operator should carefully note the following points: (1) the size, location, and other characteristics of the wound itself may be defined; (2) whether there be any escape into the uterus of any intestinal loops; (3) the relation of the child's parts to the wound; (4) whether the placenta be involved in the laceration, and (5) it may be ascertained if the fetal membranes are protruding intact through the wound. If the wound is high up, very irregular and extensive, we can hardly look for repair and should give the patient the benefit of an abdominal operation.

The child may escape through into the peritoneal cavity, and the uterine rent be closed so as to make any attempt at delivery by the vagina improper and impossible.

The author states that in a considerable number of cases of rupture of the uterus a

large hematoma will form, usually beneath the peritoneum, and the extravssated blood will make its way even out to the abdominal parietal tissues, so as to give all the discoloration of extensive ecchymoses on the skin of the side corresponding to the uterine wound. This blood is in due time absorbed and recovery is complete. This subperitoneal collection of blood makes a very serious complication in the operation of laparotomy for uterine rupture. Any attempt to evacuate the effused blood, and to reach and suture the lacerated tissues, is attended with great difficulty and risk to the patient; whereas in those cases where the wound is within the peritoneal cavity, the abdominal section may be the only proper method of treatment.

This author also reports a case of uterine rupture treated by palliative measures where the patient recovered and a year and a half later was delivered of a nine-pound child by podalic version. The cicatrix of the former rupture could be distinctly felt through the thin parietes. The author believes that there is a distinct field for the palliative treatment of rupture of the uterus, as there is also for the operative treatment.

Dr. Edward Reynolds contributes a paper on

The Treatment of Face Presentations,

in which he comes to the following conclusions:

When a face presentation is detected before the engagement of the face, and before rupture of the membranes occurs, there is always reason to hope for a spontaneous restoration of flexion. The obstetrician should therefore confine himself to the adoption of postural treatment and gentle external manipulations till the occurrence of engagement or the rupture of the membranes renders a spoutaneous flexion improbable.

When the membranes rupture early an external or bipolar version should be at once performed, in any case in which the condi tion of the cervix renders a manual dilatation of the os dangerous; but in ordinary conditions of the cervix a manual dilatation should be undertaken immediately after the rupture of the membranes, the head should be flexed by the hand, and the subsequent treatment should be operative, but its details should be dictated by the position.

When the membranes persist until the cervix is completely dilated an anterior position of the chin should be left to nature, so long as its progress is rapid and the fetal heart is steady; but when any irregularity of of the fetal pulse, or an even moderate delay at the brim, has been detected, the patient should be anesthetized and the head flexed.

The posterior position of the occiput so produced should not be left to nature, even though the os has been completely dilated by the membranes, but should always, in such cases, be subjected to an immediate manual flexion.

The anterior position of the vertex which results may then be left to nature or may be delivered by forceps.

In neglected cases in which manual flexion is contraindicated, version should be chosen, if it is practicable, whatever the position of the chin; if version is contraindicated such cases should be treated by the immmediate application of forceps to the face as such, but in the posterior positions of the chin this operation should always be preceded by a rotation of the chin to the front. In cases in which the face presentation is due to some other mechanical obstruction the treatment should be determined by the latter factor.

The abdominal methods of delivery are never indicated in uncomplicated face labor.

Dr. F. H. Davenport discusses the

Ultimate Results of Treatment of Backward Displacements of the Uterus by Pessary,

with especial reference to the Alexander-Adams' operation. The author sums up his opinions as follows:

1. In cases of uncomplicated retroversion or retroflexion of the uterus the choice of treatment lies between shortening of the round ligaments and the wearing of a pessary.

2. A cure, either anatomical and symptomatic, or symptomatic alone, may be confidently expected from the use of a pesssary in about twenty-five per cent. of all cases.

3. Where a cure is effected it is usually within a year or a year and a half after the beginning of treatment.

4. A large proportion of those not cured can wear a pessary without discomfort and do not wish an operation.

5. The operation for shortening the round ligaments should be limited to those cases where a pessary cannot be worn, to those who prefer it to wearing a support for years, to cases where vaginal treatment is inappropriate, and as supplementary to other operations.

The remaining papers in this issue are: "Symphysiotomy Versus the Induction of Premature Labor," by Charles P. Noble, M. D. "Practical Applications of the Principles of Sterilization," by Hunter Robb, M. D. "Intraligamentous and Retroperitoneal Tumors of the Uterus and its Adnexa," by William H. Wathen, M. D. "The Cystoscope," by Howard A. Kelly, M. D.

[The editor regrets that through an oversight on his part the review ol the July number of this magazine should follow that of the August number.—E. J. M.]

Variola and Varicella.

M. Andre Martin relates that two sisters, after travelling from Paris, came to reside in a house where several of the inmates were suffering from varicella. The elder sister at once contracted the affection, whereas the younger, a few days later, showed unmistakable symptoms of variola—namely, confluent pustules, distributed over the whole body, but more marked on the hands and face. Finally, a month later, the father and another sister, who had attended the invalids during their sickness, were seized with varicella. Investigation proved that neither disease existsd epidemically in the town at the time, and that its spread was confined to one house and one family.

PERISCOPE.

MEDICINE.

The Importance of Menstruation in Determining Mental Irresponsibility.

Krafft-Ebing (*Jahrbuch, fur Psych*, x., 2, 3) reaches the following conclusions on the subject:

(1) It is useful to consider the mental soundness of women during menstruation from a medico-legal point of view.

(2) It is advisable where a woman is held on a criminal charge to ascertain whether the commission of the act coincided with the menstrual period; and by "period" is meant not only the days when there is actual flowing, but those before and after as well.

(3) It is best to advise examination of the mental condition when such coincidence is established. This is indispensable when there is a personal history of neuropathic defect, of mental disturbance at the time of previous menstrual periods, or when the nature of the act reveals any striking features.

(4) When then menstrual process exerts a powerful influence on the mental life of the subject the accused should be given the benefit of extenuating circumstances in the infliction of the penalty, even although there be no proof of menstrual insanity.

(5) When the offence of crime has, in a person whose mind is impaired, occurred during the menstrual period, she must be declared irresponsible, for there is every reason to think the act due to emotional impulse.

(6) But individuals who by reason of menstrual insanity would benefit by acquittal on this ground should be considered as dangerous in the extreme and subjected during the times of the menses to close surveillance. It is best to confine them to any asylum for the insane where they will be comfortably cared for and often cured of this menstrual instability of mind.—*Brooklyn Med. Journal.*

Ice in Phlegmasia Alba Dolens.

Dr. John A. Miller (*Pacific Med. Journal*), in treating on the subject of "milk leg," speaks highly of the efficacy of the cold treatment of the disease. He first used it in 1886, and since then has used it in six cases with uniform and decided success. The procedure was in the following manner: An ordinary large towel was dipped into iced water, wrung out and clapped around the affected limb; a heavy flannel roller bandage was then applied from the toes upward to the groin. On the most painful parts, like the inner aspect of the thigh, the popliteal region and the calf of the leg, were laid rubber bags filled with ice. These were kept in place by a circular binder, independent and outside of the roller bandage. The patient was a little shocked when the cold towel was first applied, but the unpleasantness was only momentary, and then the reaction brought ease and comfort. She desired the ice bags to be renewed quite often at first, as she claimed they relieved the pain, as anything else had never done before: The pain was entirely controlled by the cold. The temperature dropped from 103° to 100° the next day, and the patient commenced to improve, which continued uninterruptedly. The towel was freshly dipped from four to six times in the twenty-four hours. As soon as the patient experienced relief, she was quite anxious to endure the temporary chill from a fresh compress, because the limb always felt better for it afterward. The towels soon become dry and hot, and this gave rise to painful symptoms again.—*St. Louis Med. and Surg. Journal.*

Renal Casts.

Aufrecht (*Centralbl. f. inn. Med.*), discusses the origin of these casts. They must either be due to an exudation from the blood, or be a product of the renal epithelium. In favor of the latter view the following facts are cited: (1) In experiments in which the author tied one ureter, the renal epithelium was seen to contain masses of a hyaline substance which latter subsequently made its way into the lumen of the tubules to form casts (2) Albuminuria may exist without casts. (3(Casts may be present without albuminuria. (4) Casts may be seen in the collecting tubes of a different color, and having such a calibre that would not have allowed them to pass through Henle's loops; the author has shown this undoubtedly local origin in the tubules in the cholera kidney and in scarlatinal nephritis.

Elimination of Phosphates in the Urine in Malarial Fever.

Rem-Picci and Bernasconi (*Il. Policlinico*), find that there is often in malarial infection an increase in the elimination of phosphoric acid during the first twenty-four hours. This they attribute to the increased ingestion of food which is so commonly desired at the onset of the illness. Almost as soon as the temperature has risen distinctly above the normal there is a very notable diminution in the amount of phosphoric acid eliminated, in spite of the fact that the amount of urine passed is generally much increased. This diminution is independent of the amount of food taken, and occurs even if at the beginning of the access a large dose of phosphate of sodium is taken, or the same drug if given by subcutaneous injection. The diminution is not proportional to the degree or duration of the fever. Immediately after the access of fever ceases there is a remarkable "unloading" of phosphoric acid, which continues for several hours, and generally compensates for the retention observed during the febrile paroxysm. If the access is cut short by quinine, phosphaturia is usually observed. In chronic malarial cachexia the elimination of phosphoric acid did not appear to be affected.

Hysterical Apoplexy.

Bischoff (*Wien. Med. Woch.*,) reports a case in a man, aged 28. Some fourteen days after severe mental anxiety, he suddenly became unconscious. On the next morning he regained consciousness, but was found to have complete left hemiplegia and hemianæsthesia including the conjunctiva. He was quite aphasic and innervated his face muscles imperfectly and slowly. There was not race of spasm about the face. On the next day it was noted that the movements of the left eye were considerably limited when the right eye was covered up. He soon began to regain power in the leg. The plantar reflex was absent, and the left knee jerk less than the right. About the seventh day the patient again lapsed into a comatose condition lasting for two hours and a half. Clonic spasm was noted on the next day in the platysma and sterno mastoid muscles. He steadily recovered power, but the anæsthesia and eye symptoms persisted. A temporary weakness in the left arm again appeared, and the contraction of the field of vision became more marked. The patient ultimately recovered almost completely. The author remarks that the involvement of the face and tongue is rare in these cases, and that Charcot's statement that hysterical affections in the face region regularly appear in the form of spasm is not borne out here. The diagnosis was certain on the third day—the left hemiplegia, the deviation of the tongue to the right, the aphasia with perfect power of writing, the hemi-anæsthesia including the mucous membranes, the diminution it the field of vision all pointing to hysteria. The affection of speech in hysteria is mostly mutism; here the patient could phonate, but not articulate. Any anatomico pathological explanation of the eye symptoms was hardly possible. The author maintains that the one-sided lesion was primary, and the unconsciousness secondary, and that it was not an example of hysterical stupor followed by paralysis; nor was it an instance of hysteria complicating organic disease.—*British Medical Journal.*

OBSTETRICS.

The Treatment of Pregnancy Complicated by Heart Disease.

Sears reports the case of a woman, having a double mitral lesion, between three and four months pregnant, who had suffered for several years with alarming symptoms of failure of compensation. After a month's careful treatment the slightest exertion would upset the cardiac balance. He, therefore, reasoning that for a period of five months she would have increased physiological demands upon her heart and at the end of that time would have to meet the tremendous muscular strain of parturition, decided to induce abortion. This was done by dilating the cervix and packing the cervical canal with iodoform gauze. Two days later the packing was removed and the fetus found in the vagina.

Sears, after reviewing the statistics of similar cases in which nature was allowed to take its course, summarizes the following propositions:

(1) That many women with valvular disease, even when situated at the mitral orifice, pass through repeated pregnancies without suspecting that they are victims of such disease.

(2) That as miscarriages are very frequent, and the chances of the child's surviving more than a few years are doubtful, if the mother's condition during pregnancy has been serious the probable fate of the latter should take so much more prominence in deciding the question of abortion.

(3) That the necessity of inducing abortion is very probable if grave symptoms have appeared during the early months or are present with an advancing lesion, or if there is a history of extreme danger in the preceding pregnancy.

(4) That if the necessity for an abortion becomes apparent, the sooner it is done the better, while the fetus is still small and the expulsive force chiefly furnished by the uterus.

(5) That the hope that relief may be given when the case has become desperate by inducing abortion is delusive, as it is possible that it only increases the danger.

(6) That marriage should be forbidden, except perhaps in very unusual cases, to women suffering from cardiac disease.—*University Med. Magazine.*

Ten Reasons Why the Abdominal Bandage Should not be Used After Labor.

1st. It is unnatural.

2d. It is liable to become soiled and hence a harbor for microbes.

3d. It increases irritation of the tired and overworked abdominal organs.

4th. It interferes with the necessity of frequent antiseptic ablutions.

5th. It is difficult to keep in place, unless made to order.

6th. It binds down the weak uterus and promotes the return of a displacement or a sub-involution.

7th. It predisposes to puerperal and cerebro-spinal centers.

8th. It increases rather than diminishes the danger of post-partum hemorrhage.

9th. It prevents digestion, assimilation, and intestinal peristalsis and tends to bladder trouble.

10th. It is unsafe to apply it by any one except the accoucheur or an experienced nurse.—W. B. Conway, in *South Med. Record.*

PATHOLOGY.

The Parasites of Cancer.

Kurloff (*Centralbl. f. Bakt.*) considers it very desirable that those engaged in investigating the supposed organisms of cancer should furnish with each published case the history of the patient, and a clinical and pathologico-anatomical account of the cancer. Seeing that in all these respects cases differ

greatly from each other, it is very probable that the parasites present also vary in different cases. Only by some such plan can we hope to systematise the results arrived at by various investigators. In the present article especial attention is drawn to the organism (*Rhopalocephalus cancerornatosus*) described by Korotneff Kurloff has found what appears to be the same body in a primary cancer of the dorsum of the hand in a male aged 80 years. The supposed parasite lay in a vacuole within the epithelial cell. The tissue was prepared as follows, small pieces were fixed in Flemming's solution and cut in paraffin. Sections were stained in various ways, those treated by safranin being the most successful. The most notable feature of this parasite is its great size; it is readily seen under a magnification of 300 to 400. It presents well-marked pseudopodia, by which movement, with passage from cell to cell, appears to take place. Kurloff is satisfied of the parasitic nature of this body. Establishing itself within the epithelial cell of the carcinoma, it leads to hypertrophy of this cell, which results in the formation of epithelial "nests."

Occurrence of Living Parasites in the Blood and Cancerous Cells in Cases of Carcinoma.

In patients suffering from carcinoma, Kahane (*Centralbl. f. Bakt.*) finds in blood from the fresh growth, and also from the finger tip, minute, irregular, amœboid, highly-refractile bodies, which he regards as parasites. These show very active rotary and progressive movements. The small bodies lie free in the blood stream, and also within the red corpuscles. The movements are kept up for an appreciable time after penetration of the corpuscle. Kahane thinks that further investigation may show morphological and biological points of resemblance between these bodies and the plasmodia of malaria. Examination in the fresh state disclosed similar bodies within the cells of the cancer. The growths examined were epitheliomata situated upon the face, prepuce, and cervix.

Meningitis Complicating Enteric Fever.

Stuhlen (*Berl. klin. Woch.*,) remarks that besides the staphylococcus, streptococcus, and pneumococcus, other micro-organisms may occasionally set up meningitis. He relates the following case in a man whose wife and two children were already seized with enteric fever. After a few days of *malaise* he complained on July 28th of headache, shivering, and constipation. He was admitted three days later. On August 1st there was blood in the stools; stupor, with restlessness and delirium, supervened. On the next day sudden collapse appeared, from which he rallied, but the stupor persisted. On August 4th there was rigidity of the neck, and slight icterus was now observed. He died about the fourteenth day. Besides the lesions in the alimentary canal, there was a purulent cerebro-spinal meningitis. Plate cultures showed colonies having all the characters of those of the typhoid bacillus, and further investigation confirmed this view. The clinical appearances, the existence of enteric fever in the house, and the presence of the typhoid bacillus (in pure culture) in the meningeal pus made the diagnosis certain.—*British Medical Journal.*

Trophic Disturbance in Wasting Palsy.

Prautois and Etienne (*Rev. de Med.*) relate an exceptional case of osseous and articular trophic changes in a man, aged 48, affected with progressive muscular atropy. The disease began some thirteen years ago. On admission, there was atrophy of the muscles of hands and arms. The sterno-mastoid, trapezius, pectorales, infraspinatus, serratus magnus, and neck muscles were affected on both sides. The legs were much less involved. The right arm could not be lifted to the vertical position, and he had great difficulty in raising his head. On the right side the head of the humerus was dislocated upwards, and the sensation of rubbing two rough surfaces together could be obtained here. A large, irregular osteophyte grew from the scapula. There was in addition a bilateral carpo radial subluxation. On the left side the outer end of the clavicle was morbile and and dislocated, and creaking could be felt in the shoulder-joint. The patellar reflexes were present; there were no ankle clonus, pains, or inco-ordination. The reaction of degeneration was present in the affected muscles. The pupil reaction was normal. There was no evidence of previous rheumatic disease, and the articular affection was certainly comparable to that seen in locomotor ataxia. In all probability it was due to a spinal cord lesion similiar to that producing the atrophy, but of hitherto undetermined site.—*British Medical Journal.*

ARMY AND NAVY.

CHANGES IN THE U. S. ARMY FROM AUGUST 17, 1894, to AUGUST 25, 1894.

Leave of absence for two months, to take effect on or about Septemder 1, 1894, is granted Capt. John L. Phillips, Assistant Surgeon.

Leave of absence for three months, to take effect on or about October 1, 1894, is granted, 1st Lieut. Madison M. Brewer, Assistant Surgeon.

Leave of absence for one month, to take effect on being relieved from duty at Fort Supply, O. T. is granted Capt. William H. Corbusier, Assistant Surgeon.

1st. Lieut. William H. Wilson, Assistant Surgeon, will be relieved from temporary duty in the Department of Dakota by the Com'd'g General of that Department when his services are no longer required with troops in the ffeld and will return to his proper station.

Leave of absence for one month with permission to apply for an extension of one month, is granted Capt. Alfred E. Bradley, Assistant Surgeon, U. S. Army.

ORIGINAL ARTICLES.

CHRISTIAN SCIENCE AND THE MEDICAL PROFESSION AGAIN.

F. C. HERR, M. D., Ottawa, Kansas.

"When the mind is once pleased with certain things it draws all others to consent and go along with them, and though the power and number of instances that make for the contrary are greater yet it either attends not to them, it despises them or else removes them by a distinction with a strong and pernicious prejudice to maintain to the authority of the first choice inviolated. And hence in most cases of superstition as of Astrology, Dreams, Orneus, Judgments, etc., those who find pleasure in such kind of varieties always observe where the event answers but slight and pass by the instances where it fails, which are much the more numerous."—Bacon's Novum Organum.

"Christian Science and Its Relation to the Medical Profession," is the subject of a paper read before the Pennsylvania State Medical Society, and published in The Medical and Surgical Reporter for August 11th. I am glad Dr. Longsdorf read the paper, and gladder still that it was published in The Reporter. Her warning that something must be done with this monster of scientific and religious distortion is timely. Her paper will have served a good purpose if it does nothing more than stimulate thought and investigation into the audacious pretenses of this pernicious and fulsome doctrine.

In this paper I shall endeavor, as far as possible, to take the subject of christian science out of the realm of occult things and bring it within the range of intelligent thought and comprehension.

Christian Science is not a new thing—it is simply a new name for a very old thing. In its phenomena (by which I mean its reputed and actual triumphs in the healing art) it can be traced back to the twilight of fable, and even beyond that dimly remote time, until its argument becomes lost in its very antiquity. But the name is not only new, but seductive and delusive, completely adapted to the highest ends of what may justifiably be characterized as the Black Art. I am well aware that such an imputation is resented by the defenders of this new heresy, but its *modus operandi* to them is not more intelligible than was the medical philosophy of the Rosicrucian physicians who applied the salve to the weapon instead of the wound itself.

The "Dreamers of the Gods" of ages ago, and the "Masters or Guardians of Divine Thought" of the early northern Indians, had as much of an intelligent basis as has our modern "Christian Science." In those distant days such strangely absurd beliefs were not explained and defended by the same dexterous use of language that is now so noticeable. Mrs. Eddy's work is nothing but a lofty pretense at a philosophic exposition of her own introspective mental states, and an attempt to apply her deductions to the universal mind. She has fallen into the same egregious error that has characterized the intellectual flights of the mediæval sophists, who wrote volumes filled with smooth flowing sentences, but in whose volumes a Philadelphia lawyer could not find any trace of reason or sense. With unique skill and consummate finnesse, Mrs. Eddy

plays upon the words fear, dread, sin, sickness, death, spirit, God, etc., but with all her ingenuity and cleverness she fails to break the bolts that bar the realm of mind and bring it within the pale of experimental research. But she is here. Her works are among us. Her votaries are up and doing, zealous and enthusiastic, preaching and spreading the new science. Dr. Longsdorf says "some form of definite action should be taken, whereby we could cope successfully and with dignity with what must otherwise be a dangerous foe."

Against all the audacity and impious assumption of these shameless pretenders we must oppose something. What shall it be? I submit it can be only *light! knowledge! truth! science!*

It will not do for medical men to stand aghast at the achievements of these montebanks. It will not retard their cause, nor accelerate ours, to characterize them as imposters and their work as an imposition. We must proceed along other lines. We must undeceive the people by demonstrating to them that christian scientists possess no power and no knowledge that medical men do not possess. Where is the enlightened physician who cannot cure disease, not all disease, by purely *mental therapeutics?* Here is the "sin" of the medical profession. From time without memory these agencies have been used, sometimes with marvelous effect, and yet doctors condemn, and make strenuous effort to cast upon them disrepute. A doctor should never lift his hat in the presence of such a distorted monster as christian science. Every man in the medical profession (and woman too) can do just what these christian scientists can do. He can do more, for his diagnostic skill endows him with a nicety of discrimination in selecting subjects that the ordinary christian scientist cannot have.

I submit that in our medical schools and medical text-books insufficient attention is given to the *remedia psychia* of Pereira. I submit further that mental influences as a factor in the causation of disease do not receive a tithe of the consideration to which their importance entitles them.

The poet Churchill wrote:—

"The surest road to health, say what they will,
"Is never to suppose we shall be ill;
"Most of those evils we poor mortals know
"From doctors and imagination flow."

This picture of the English poet is overdrawn, and yet every intelligent physician knows that there is more truth than poetry in the verse. Most readers are familiar with the incident which followed a discussion between Erasmus and Sir Thomas Moore on the subject of transubstantiation. Sir Thomas vainly endeavored to convince his friend of the real presence, and assured him that if he would believe he would be convinced beyond a doubt. Upon leaving Moore's house he borrowed his pony, and did not return it, but sent the following lines:—

"Remember you told me
"Believe and you'll see;
"Believe 'tis a body
"And a body 'twill be.
"So should you tire walking
"This hot summer tide,
"Believe your staff's Dobbin
"And straightway you'll ride."

The celebrated Dr. Rush once wrote, "I have frequently prescribed remedies of doubtful efficacy in the critical stage of acute disease, but never till I had worked up my patients with a confidence bordering upon certainty of their probably good effects. The success of this measure has much oftener answered than disappointed my expectations."

In the fifth edition of Flint's Practice of Medicine, page 116, these observations are made: "In the management of cases of disease, mental influences are often of not a little importance. Hopefulness and a strong will are curative agencies which are frequently powerful auxiliaries to remedial remedies, and they are sometimes more potent than drugs. Certain disorders may be produced and prolonged indefinitely by mental causes. A cheerful mien and manners calculated to inspire confidence are to be cultivated as highly useful professional attainments." Dr. Flint in the closing years of his eminently useful life had a keen appreciation of the value of psychical agency in the treatment of disease.

I am quite sure that Dr. Longsdorf makes a grave error when she says that "it (christian science) must not be confounded with hypnotism, animal magnetism, faith or mind cure, spiritualism, clairvoyant or other trance, or the old-time powwowing process." If christian science is not these things we have abundant reason for alarm. We may well then cry out "What shall we do to be saved?" But it is the same old imposter in masquerade dress,

and with an extraordinary adaptation of means to ends, the garb distorts the vision of the subject so that things are not what they seem. The history of christian science, so far, is almost a counterpart of the early history of mesmerism. It is amazing that a learned profession, like medicine, should look with any degree of wonder upon the manifestations of an art that has grown musty with age, and that scientific bodies, time and again, have investigated with always the same result.

The West has suffered from the infection of the christian science craze as it has from chinch bugs and grasshoppers. A few years ago medical men found their paths crossed at almost every turn by this bold pretender. It is not so now, though the creature still moves among us, but with much less of its former strut and bravado.

I remember the heyday of christian science in this community. I recall the case of a young man in whom an empyemic abscess had made a spontaneous opening through the chest wall, and who was advised by the writer to have an operation done as the only means of saving life. Within twenty-four hours a christian scientist intruded her presence upon the unfortunate young man, and, standing in full view of copious issues of pus from the opening in the chest wall with each respiratory effort, assured the poor victim that "nothing ailed him," that "disease was a myth," that he should "go and sin no more by employing a doctor." He went in less than a week. This case did much to place christian science under ban in this community.

This case is illustrative of the point I wish to emphasize, namely, that the good things in christian science, the *remedia psychica* of Pereira, the *mental influence* of Flint, the *psycho-therapeutics* of Tuke, cannot be ignored by the physician who aspires to the fullest measure of success in his profession. Unlike the ignorant christian science pretender, he has the power of discrimination between the cases that can be cured by *psycho-therapeutics*, and those that imperatively need the assistance of art, or the *remedia physica*.

I submit that the enlightened medical man should seldom fail in the successful use of psychical agency in the treatment of disease. This success or failure, however, will turn upon his discriminating judgment in the selection of cases. The case of empyemic abscess just cited is in point, and I may be pardoned citing another case equally in point, though at the other extreme of the pathological state. The patient was a maiden lady, twenty-eight years of age. For eight years she had been an invalid confined to bed. She employed many doctors and had been treated for many maladies, among them uterine displacement, ovaritis, cystitis, nymphomania, masturbation, and, as a *dernier resort*, she had been advised to contract marriage. A very careful examination of this case disclosed the astonishing fact that no organic disease of any moment existed, and I am almost incredulous myself when I recall the fact that a single dose of *psychic* medicine restored the eight-year invalid to health and usefulness. This was a case in which all the drugs in the materia medica would have availed nothing, and one, too, in which christian science only needed the opportunity to achieve a brilliant triumph.

The successes of christian science are no credit to that craft, but they are a distinct reflection upon and discredit to the medical profession. I come back then to the affirmation that enlightened medical men can do all and vastly more than these christian science pretenders can do, provided they use the gifts God has given them, and the means science has furnished them for intelligent discrimination and judicious enlightened treatment.

To scoff at the potency of christian science (?) or *psycho-therapeutics*, because the influence is subtle, unseen and unfelt, is not worthy a philosophic mind. Who would scoff at the dire potency of a drop of hydrocyanic acid because he does not understand its *modus operandi*? And is the one less mysterious than the other? Who can explain either? Both are verities, and in the never ceasing onward march of science both may some day be made clear to our comprehension.

I have already extended this paper beyond the limits prescribed and close with the observation that not a single result of christian science in its relation to the cure, or modification of disease, has any rational explanation outside the pale of *psycho-therapeutics*. The "divine mind" of the christian scientist is a dream, a chimera, a hallucination, precisely as were the "Masters of the Divine Thought" of the early northern Indians.

TREATMENT OF PNEUMONIA.*

W. C. HUMPHRIES, M. D., Acworth, Ga.

In presenting this article on the treatment of pneumonia, I intend only to give a brief *rèsumé* of the line of treatment I have found most successful, and will confine myself mostly to the acute lobar variety.

I live and practice in that portion of the state noted for its salubrious climate, pure water and its being as a rule free from malaria and other morbific emanations with which our friends farther south have to contend. The majority of cases with which we come in contact assume from the beginning the sthenic or high grade type and require active or depleting measures. If called to treat the patient in the first stage of the disease I resort to moderately active catharsis and an agent that will arouse the dormant secretions and assist nature to eliminate from the system the effete products produced by the disease.

For this purpose I find no better remedy than calomel, not only because it meets the indications mentioned above, but also on account of its superior antiphlogistic powers, its defibrinating the blood, its antiseptic properties, etc. I usually prescribe from six to ten grains for an adult, in combination with Dover's powders or some preparation of opium and bismuth subnitrate. I generally compound my own prescriptions, and as a rule divide this into three or four powders, and direct that a powder be given every two hours, best in capsules. If a patient can not swallow the capsules, I mix the powder in a teaspoon with a small amount of sugar or syrup, to which is added water, a sufficient quantity for dilution. After an interval of a few hours, I direct this to be followed with a brisk saline cathartic which empties the alimentary canal and in the majority of cases reduces the fever, lessens the pain, mitigates the excessive amount of congestion in the lung, and adds in many ways to the welfare and comfort of my patient. This prescription, perhaps, is a very old one, yet it is surprising to see how potent it is, in many cases rendering further medication almost unnecessary.

My next effort is directed to reducing the force and frequency of the heart's action, which in most cases of this type is very strong and rapid. The blood vessels in the inflamed lungs are strutted with blood, the lung tissue is turgid and filled with the products of inflammation, causing pain, more or less excessive, and dyspnœa in proportion to the amount of lung tissue involved. The rational treatment, it seems to me, is to reduce the force and frequency of the heart's action. For this purpose I have tried several remedies, such as aconite, gelsemium, the coal tar derivatives, etc., but none of them have given so great satisfaction or such uniform results in my hands as veratrum viride. I use this oftener than any other heart sedative in this disease and it seldom fails me. I do not give it to such an extent as to produce nausea, but in small and often repeated doses. I find that three mimims given every three hours will have as good effect as larger doses, and is not so apt to produce a disturbance of the digestive organs.

With veratrum I combine what I consider one of the sheet-anchors in the treatment of this disease, namely, turpentine in the form of an emulsion. In my opinion, there is not a remedy in our pharmacopœia so potent or productive of good results in this or the vast majority of diseases with which we come in contact, as turpentine. Being a product of our own state, it is plentiful and easily accessible to all, yet it is surprising to see how reluctantly some physicians use it, and what little importance they attach to it. I use it freely, both internally and externally, and find it especielly useful in those conditions where the tongue has a tendency to become dry and red, and the force of the pulse begins to show adynamia. In small doses it prevents gastric and intestinal irritation, assists in keeping the secretions aroused, aids the emunctories of the body, acts as an astringent on the arterioles of the inflamed lung, and soothes the inflamed mucous membrane of the bronchial tubes, assisting nature to throw off the collection of mucus from them.

With veratrum and turpentine I pre-

* Read before the Georgia State Medical Association, April, 1894.

scribe various expectorant mixtures, such as squills, wild cherry, elixir pinus compositus, usually some preparation of opium, etc., varying them from time to time as the symptoms and progress of the disease demand. If the bowels become constipated, a mild purgative should be given occasionally to keep them open, or what, perhaps, is better, repeat the powders mentioned above, especially if the tongue is coated and the cough is tight.

In regard to the use of the coal-tar derivatives which have recently come into vogue, my experience has been rather extensive, and in some cases I prescribe them with marked benefit, while in others with not so much success. In cases complicated with violent headache, especially if neuralgic in character, and pains in the back and extremities, they often act like a charm. In some cases I get a reduction of temperature and free diaphoresis with them; in others I do not. I consider them splendid adjuvants in the treatment of this disease. Of the various preparations I have tried, I have always gained better results from the use of acetanilid.

I will refer briefly to external applications. I have used various forms of liniment containing turpentine, and the one I consider the best is the old-fashioned volatile liniment, composed of equal parts of olive oil, turpentine, and aqua ammonia. Other applications, such as mustard, spongiopilin, hot poultices are very useful and should not be omitted. Of all the external applications I have used so far in the treatment of the sthenic type of this disease, I have found none that gave me so great satisfaction as the application of a large sized blister, and I think the sooner it is applied the better it is for our patient. I am aware that there is a great diversity of opinion on this subject in the profession, and it has been discussed time and again, but a recurrence to it will not be amiss, for it is a subject that demands the attention and earnest investigation of every thinking practitioner.

The present status of the practice of medicine is due to the wide experience and investigation of men who have devoted their lives to the profession and have spent many years in endeavoring to eliminate the wrong and establish the right. To the collation of the experience of such men our profession owes the rapid progress it has made in the last few years. These are the guide-boards that must point us younger members to the road that will ultimately lead us to success. Excuse this slight digression, but I find a tendency with some of our younger practitioners to wander off into theories that have not been sufficiently tried or proven and exclude the bright gems of thought that have been handed to us from the store-house of ripe experience.

At the meeting of the Association in Columbus, the subject of blisters was discussed *pro* and *con* with a great deal of fervor, and especially by one whom we all love and revere for his ripe experience and profound medical knowledge. We know him to be a physician of rare ability and one on whom we can all rely. During the discussion on this subject he said: "If you wish to do me honor when I am dead, say to the coming generations and inscribe on my tombstone, 'Dr. Griggs used to blister in pneumonia.' I am willing to stand the test of time on it until Gabriel blows his horn."

In this same discussion our lamented Dr. R. O. Engram, in answer to the question why he blistered, said: "I blister because it relieves pain, and my experience has been that patients do better with blistering than without it." Several of the older members entered upon this discussion and all seemed to be united upon one thing; to blister, blister well, and repeat if necessary.

I am associated with my uncle, Dr. J. R. Humphries, who has practiced medicine for over thirty years and his advice to me has always been to use blisters in all stages of the disease, the earlier the better, and to use them freely.

I refer to these men not only because of their long and varied experience as physicians, but because they are our next door neighbors and better understand the diseases we treat than those who practice in a different latitude and are not so familiar with them. My own experience with blisters has been very satisfactory, and I have yet to see a case where I used them and regretted it. Of course, they are to be used circumspectly in the very young or very old.

In the second stage of the disease the foregoing plan of treatment is generally carried out, making such additions and changes as necessary. I find it sometimes necessary to commence with some prepar-

ation of ammonia, such as carbonate, which I find to be the best, and also to add alcoholic stimulants if the vital forces show a tendency to weaken.

In the third stage or stage of resolution, the treatment should be supportive, and tonics, reconstituents, etc., should be given according to circumstances and the demands of the system. In those cases that assume the low grade or asthenic form of the disease from the beginning, we must be careful not to carry our depleting measures too far, and to commence our supportive treatment early in the disease. In these cases blisters should be used circumspectly.

In the treatment of pneumonia, as in all diseases which afflict humanity, the physician should not forget the *vis medicatrix naturæ*, and that over-medication in many instances does more harm and retards the patient's recovery longer than would no medicine at all. He should be ever on his guard, willing to accept that which his own experience and that of others teach him is right, and reject that which is wrong, remembering that good common sense and sound judgment are the essentials necessary for success.

THE CONTAGIOUSNESS OF DIPHTHERIA.*

JOHN R. HAMILTON, M. D., Port Dover, Ont.

Two years ago, when reading the reports of this association, I was very much interested in a paper by Dr. Wilson, on cases in practice wherein diphtheria seemed to be carried by a third party, and which evoked much discussion among the members at the time; the majority, I have no doubt, still clinging to the belief that the disease is not communicated in that way. And in this belief we have nearly all rested, although we admitted at all times its epidemic nature, and the theory of direct contagion is, we all know to our sorrow, only too well founded. The untimely deaths of many young physicians, estimable nurses and loving mothers, caused by coming in too close contact with the poison-laden breath of the dying child, attest too clearly this fact. But while we admitted the theory of direct contagion in this disease, I think the majority of medical men have been unanimous, or almost so, in thinking that when asked by friends if the disease was transmitted in the manner that bacteria of other zymotic diseases are transmitted, they felt justified in giving an adverse opinion.

And why should we not cling to this belief when the opinion is endorsed by men of large experience. Squire, of London, says: "I know of no instance of the disease being carried from one house to another by the passage to and fro of those who were themselves unaffected." Bretonneau's theory of direct contagion, and Trousseau's inoculation experiments give nothing to medical literature to warrant belief in the disease being propagated by a third party. Now, we have had many men of large experience to contribute their opinions on diphtheria, one of the longest known and most dreaded of all diseases, its causes, its many and varied types, its paralysis and other sequelæ, its multitudinous therapeutics, many of them very widely different. One author in England, for example, in giving the differential points between scarlet fever and diphtheria, says the latter is found more frequently in rarified atmospheres, in the sandy hills, an Alpine region in fact, whereas we who have practiced for years in the low-lying districts of this Province know the converse to be the fact, and that the drainage of our loamy soils has had effect in extinguishing the disease.

A short time prevous to reading Dr. Wilson's paper in February, 1892, I was called to attend a family in one of the townships, in which a little boy of seven years was prostrated with this disease; afterwards one of the young women of the family was taken with it. The little boy had the asthenic form followed by paralysis to which he succumbed. The young woman recovered. During the time of their illness a relative, the mother of a large family, visited them, remained only a day and returned to her home nine miles distant. Four or five days after-

* Read before the Ontario Medical Association, June, 1894.

wards I was called to attend two of her children, one of whom had already hemorrhage from the throat and nose, and in a few days her whole family of children and the servant girl contracted the disease. There was no diphtheria in the neighborhood of this family either before or after this event, neither had the mother any symptom of the disease.

This case was so striking that I have been watching for corroborative evidence as to this method of propagation. In this country, so far, I only find in addition to Dr. Wilson's testimony, that of the Medical Health Officer for Toronto, for 1892. He says, in an essay before the Provincial Board of Health: "As an example, I may state that an infant living in one of the suburbs of this city was sent away from home where the disease existed for fear of contagion. The baby was successively sent to three families living in remote parts of the city. The baby took no sickness, but diphtheria occurred in all the three houses, two of the infected children dying."

Any contribution to the knowledge we already possess of a disease which, during the past few decades, has done more than any other incidental to childhood to prevent the increase of population, must be welcomed by all workers in the cause of science, as we have yet much to learn as to the causes which may lead to an outbreak of this or any other zymotic disease. After going through a labyrinth of opinions we are glad to reach the vantage ground of a *specific* cause, which we are now supposed to have in the bacillus first discovered by Klebs and afterwards largely experimented with by Loeffler. This is now the generally accepted cause of the disease, as the cultures of these bacilli produced the fever and depression when injected into the circulation of the rabbit, and also the paralysis which we know to be a common sequel of this disease due, no doubt, to the rapid degeneration of the nerve cell or, as Kauffman asserts, to a toxic neuritis. This bacillus, we are given to learn, produces in the tender epithelial mucous membrane of the fauces a ferment which, when absorbed, forms albuminoids by digesting the proteids, thus acting, as do other pathogenic microbes, in producing or rather manufacturing a chemical poison.

The question we, as practical men, appear to have yet to learn is, Does the bacillus of Klebs act at all in such manner as the bacteria of other zymotic diseases, as scarlet fever, small-pox or measles? Will the physician use the same caution when attending diphtheria that he would if he encountered a case of puerperal septicæmia? And does he do his whole duty if he neglects to warn visitors of the danger of contagion by conveying the disease to others unwittingly?

Treatment of Whooping Cough.

Dr. Variol recommends in the treatment of this disease the following formula, of which a dose should be given in the morning, afternoon, and evening in a little sweetened milk:

℞ Potassii Bromidi ....5ii.
Tincturæ Valerianæ.....5ii.
Aquæ.....℥ixss. Misce.

To infants, three teaspoonfuls; to children of from two to five years, three dessertspoonfuls; and to children of from five to ten years, three tablespoonfuls. An hour afterwards he gives the same quantity of the syrup of turpentine. This treatment combines the action of the balsams on bronchial secretion by the turpentine, and of the antispasmodics by the bromide of patassium and valerian. When the *râles* in the lungs are general, he administers powdered ipecacuanha in doses of seven to fifteen grains in the morning to cause expectoration of bronchial mucus. He advises that, where possible, children should live in the open air. To avoid serious broncho-pulmonary trouble in winter, change of climate ought to be secured. They ought to be fed frequently, but with small quantities, rich in albuminoids and easily assimilated (eggs, meat-juice, raw meat). Tonic treatment ought to be conjoined, such as the vinum quininæ, or the syrup of the lactophosphate of lime.—*Lyon Medical.*

Cancer of the Ovary in a Child.

—Gussenbauer (*Wiener Med. Wochenschr*, No. 17, 1894) operated last year on a little girl, aged 8 years. A tumor, double the size of a man's fist, occupied the right half of the abdomen, and had been diagnosticated as a sarcoma or teratoma. It proved to be a carcinoma, and was successfully removed. Half a year after the operation the patient was in good health, and there was no sign of recurrence.

COMMUNICATIONS.

PULSATIONS OF THE AORTA IN THE EPIGASTRIUM OF NERVOUS ORIGIN.*

PROF. POTAIN, PARIS, FRANCE.

We have in the ward Piorry, a female patient who offers a complex picture of symptoms. Profoundly anemic, suffering some time from neurasthenic symptoms, the least work exhausts her, she has points sensitive to pressure in the facial nerves, and the last dorsal and the first two lumbar vertebræ are sensitive to pressure. She does not experience a sensation of weight on the vertex, but suffers from orbital neuralgia. Her digestion is faulty, she has flatulent dyspepsia, pseudo-membranous enteritis, with constipation and a progressive exhaustion of her whole system. Her abdominal organs are movable, especially her right kidney, which descends to the upper crest of the iliac fossa.

But that which most attracts one's attention is a pulsation in her epigastrium, which is very troublesome, and especially so at night, when it robs her of her sleep; it is so violent as to lift one's hand if laid upon her epigastrium. On auscultation, a pronounced diastolic murmur is to be heard. In spite of this her heart is normal, pulsation in the crural vessels is synchronous with that of the heart. A diagnosis of aneurism is not to be made as would have been done in times past, simply because this pulsation and murmur of the abdominal aorta were audible. Neither do I wish to deny that diagnosis of the aneurism of the abdominal portion of the aorta is difficult, particularly when it is situated in the upper portion of that cavity. Stokes has reported a case of a lawyer who suffered from atrocious pains in the epigastrium, and who not only consulted a number of eminent English physicians, but also Andral, in France, who all declared that he was a sufferer from dyspepsia. One day his aortic aneurism burst and he died suddenly.

Aneurism of the aorta was suspected in our case, and search was made for it, for in actual aneurism there are present those characteristic signs, dorsal and epigastric pains, and especially in the lumbar region, which are often terrific and of great extent. They come in crises and cease completely in the intervals. They are aggravated by movement, walking about and pressure. Besides there is dysphagia, dyspepsia and vomiting. A second characteristic series of symptoms is furnished by the abdominal pulsations, but to diagnose an aneurism one should not only bear in mind the intensity of these pulsations for there are aneurisms which are accompanied by very slight pulsation. Thirdly, there is to be heard a murmur which is mostly single and sometimes double. In our patient we actually meet with this triple series of symptoms—pains, pulsations and murmur. But, if we examine these carefully, we shall see that they differ from those associated with aneurism.

The murmur is intense, but it is an artificial murmur produced by pressure exercised by the stethoscope which, partially occluding the artery for the time being, causes the blood to pass through the narrowed lumen, in vibration, and produces a murmur. If you apply your ear directly to the epigastrium you will not hear this souffle. If, at the same time that you listen with the stethoscope, you control the pulse in the femoral arteries, you will remark that there the pulse-wave becomes less and less, to disappear, finally, when the murmur is greatest by pressure of the stethoscope; easily explained, for the greater difficulty the blood current has to encounter in the aorta, the greater the pressure behind. Let us examine the epigastric pulsations. It is known that these may arise from a number of causes; transmission of the heart-beat to the liver and to asystolia. This latter cause can not be considered

* A clinical lecture delivered at the Charité Hospital, Paris.—Translated from *La Gazzetta degli Ospitali*, No. 79, 1894, by F. H. Pritchard, M. D.

for the heart is normal. Then again, there are subjects who present regular nervous contractions of the diaphragm which with marvelous and rhythmic motion may simulate the heart pulsations; but one only has to count them to see that they are less in number than the beats of the heart. Finally, there are certain neurasthenic patients who have pulsations in the epigastrium, but these do not show a tendency to expansion; this is characteristic of these patients and our patient is one of them.

Pulsations of nervous origin have long been known; Hippocrates mentioned them. Lancisi, in recent times, has given an accurate description of them, showing that they are observed in nervous patients, in hypochondriacs, hysterics, and in neurasthenic and exhausted individuals. Laënnec also met with them; and Stokes, finally, described them, having met with them in nervous and dyspeptic patients, and pointed out that they were especially to be observed at the menstrual period and at the beginning of pregnancy. They are especially frequent in nervous subjects.

In our patient the pulsation is not expansile; this may be easily appreciated by pressing the flaccid abdominal walls down upon the aorta which may be felt between the two fingers. It will be seen that its calibre does not vary. The pain is also not that of an aneurism. The pain of which our patient complains is especially nocturnal, a peculiarity which is not observed in aortic aneurism; again, it is not as intense as that of aneurism, where the patients grind their teeth and roll on the floor, with agony. The pain, finally, is epigastric and not dorsal, and though the last dorsal and first two lumbar vertebræ are sensitive to pressure there is not the terrific pain of aneurism. Therefore, in our subject it is purely nervous; she has also, as we before stated, associated neurasthenic symptoms. Besides she presents stigmata of hysteria, anesthesia of the pharynx and analgesia especially of the right side. Yet disturbances of vision are lacking, so that the neurasthenic symptoms are the more conspicuous and we may safely say that she is neurasthenic, with traces of hysteria. These epigastric pulsations are of neurasthenic origin, with no trace of aneurism.

Did these pulsations arise from this disease, neurasthenia? We had remarked that the abdominal organs of our patient were somewhat relaxed; the same holds true of the abdominal aorta, which is moveable and insufficiently fixed at its insertions and along its course; in fact, the vessel is displaceable under the finger.

Now this abnormal mobility of the viscera, in her case, dates back several years to her last confinement and it gives rise in all probability to the dyspepsia which we mentioned before. The question arises how the aorta comes to pulsate so violently while the remaining portions of the arterial system beat normally. Galen, who admitted that the arteries were provided with an expansive force of their own, would have found an easy explanation. To-day, since we know the laws governing circulation, this will not hold. We know that expansion of the arteries is but due to contraction of the heart. But, the pulsation of the arteries does not depend alone upon the mode in which the blood enters the arteries, but also upon the way in which the vessel wall reacts, so that the more that it resists the blood-wave the greater will be the intensity of the beat. Here this mobile aorta resists badly the advancing blood and transmits the violence of the heart impulse to its walls.

Possibly, a slight degree of aortitis might be added to this picture, but this is doubtful. Firstly, abdominal aortitis is very rare. It has been demonstrated to affect the thoracic portion by preference. In necropsies where the abdominal aorta has been found to be affected the thoracic portion has been also found involved. In our subject there are no signs of aortic involvement.

The treatment? Let us confess it at once. Our means of treatment in this affection only too frequently are inactive, and the pulsations will remain for years and years, in spite of all treatment. Yet if they do disappear a favorable prognosis may be given for with them, the other nervous symptoms vanish. Is the neurasthenia dependent upon this enteroptosis? Glenard's disease? I doubt it. Neurasthenia is derived from and dependent upon a number of causes. We shall treat the anemia and nervous symptoms by rest and appropriate diet, which are carried out in a hospital. Other measures we shall reserve till later, when a decided improvement has been obtained.

INCONTINENCE OF URINE IN CHILDREN, TREATED WITH ATROPIA.

[ABSTRACT.]

T. P. SATTERWHITE, M. D., LOUISVILLE, KY.

Incontinence is a malady that is more frequent in boys than girls. It may come on at any period of childhood life, and often continues until puberty, if not relieved. Many persons having the control of such children resort to punishment for a cure; the ignorant, and I regret to say more intelligent people, are often cruel to the little subjects.

It should be the duty of all medical men, whenever they are consulted on this subject, to take especial pains to explain that the trouble is beyond the control of the child, that punishment is not only fruitless, but absolutely cruel, and not infrequently assists in perpetuating the habit.

The causes of incontinence are numerous requiring careful analysis to determine the source. Simple enuresis is purely a nervous trouble. That occurring not only at night but during the day may be caused from some congenital malformation or from reflex trouble. The nocturnal incontinence is far more frequent and less serious than when it occurs both day and night.

Some of the causes that produce this affliction are, atrophy of the bladder, overflow from vesical paralysis, phimosis or adherent prepuce, leucorrhœal discharge in little girls, calculus in the urethra or bladder, an impacted fecal mass in the rectum, the round or thread worm, or any rectal or intestinal irritation; in fact, irritation of the remotest part of the body may cause incontinence. Cystitis will cause loss of control of the bladder and when severe enough there will be no difficulty in determining the cause in this instance. Indigestion is a prolific cause, excessive acidity of the urine frequently an exciting cause. Improper feeding at night or late in the evening may produce gastric disturbance which, by its reflex irritation, causes wetting of the bed. When the cause cannot be discovered our treatment will of course have to be experimental. The general health in all cases should receive our first attention. The disease cannot be cured as long as the digestive apparatus is disturbed. Poor health is a potent factor in maintaining enuresis. The child should have a liberal amount of strictly wholesome food; a very light supper and but little fluid during the evening. If there is hyperacidity of the urine that must be corrected,—we must see that the patient is kept in the best possible general health and remove any reflex trouble that may be discovered.

The treatment by belladonna has been a practice of such long standing that probably every member of this Society can remember when he commenced the practice of medicine, this remedy was recommended and used. Various results have been obtained from its use, but its long continued employment in this trouble shows its usefulness notwithstanding the varied experiences of practitioners. This varied experience is due in my opinion to two causes; first, that the incontinence was not due to a neurosis simply but to a reflex trouble which required surgical interference; second, that the remedy was not pushed to its full physiological effect and continued long enough.

When the smallest physiological dose of atropia is administered the only symptom is dryness of the throat and mouth, possibly some disordered vision. When a larger amount is given this dryness becomes more intense and is associated with redness of the fauces, dilated pupils, disordered vision and possibly diplopia. Often from the first, certainly after a short time, in all cases the heart's beat becomes rapid, and after a large dose of the alkaloid, exceedingly rapid, often accompanied by a peculiar red flush on the face and neck, which may spread over the whole body. In very severe exhibitions of the rash, desquamation of the skin sometimes follows. Intelligence may remain perfect, but there is generally some lightness of head, gidi-d ness and confusion of thought, as well as a staggering gait. Even with doses that are medicinal there are spectral illusions. Drowsiness is not a general or at all char-

acteristic symptom. When a decidedly poisonous dose of belladonna or its alkaloid has been taken, all these symptoms are intensified; sometimes the patients are exceedingly violent and convulsions may appear, followed by stupor and paralysis. Lividity of the face, showing imperfect areation of the blood, is not seen in atropia poisoning, except in a stage of most imminent peril. Death is preceded by marked heart and respiratory failure.

Upon the muscular structure of the heart itself atropia acts as a depressant, but it would have to be taken in very large amounts to be apparent. On the other hand atropia acts, it is claimed, on the cardiac nerve centers as a stimulant, and unless taken in very large amounts does not destroy excitability of these nerves.

Evidence is directly in favor of the fact that atropia in small doses contracts the capillaries, and only when poisonous doses are given do they become dilated. Atropia acts on the peripheral filaments of the nerves, it is mainly eliminated by the kidneys, and its local action on the nerve filaments of the bladder, I have no doubt, is one of the modes of relief for incontinence, when the interior of the bladder is the seat of the trouble. We are all familiar with the local action of belladonna to relieve pain as in myalgia, lumbago, pleurodenia, etc.

In the last eighteen months I have treated five or six cases of nightly incontinence, all of whom responded satisfactorily to the atropia treatment when administered to its full physiological effect. In all my cases I used the metric granules manufactured in Philadelphia, commencing with the $\frac{1}{500}$ of a grain three times per day, increasing the dose gradually for the first two days. After that the increase was more rapid until there were some decided symptoms of distress; even then the dose was continued cautiously and the toxic symptoms would often disappear without decreasing the amount. In only three cases did I have to gradually decrease the dose that was being administered. It is also necessary in the treatment to require the child brought under your daily observation to consider the propriety of increasing, maintaining or decreasing the medicine. I find we cannot intrust to the parent the dose that is to be administered, and it is not improbable the mental effect of visiting the doctor every day is beneficial.

In one case a boy æt. nine years had wetted the bed every night from birth, and seldom less than twice a night. The first dose administered was $\frac{1}{500}$ of a grain; it produced such nausea with vomiting and general redness of the surface, that his parents were alarmed. I decreased the dose slightly for several days; the child that week soiled the bed only three times. The dose was then gradually increased daily with the result, at the end of the second week of a slightly improved record. The dose at the end of the third week had gotten to $\frac{1}{100}$ of a grain three times per day, with the result of additional improvement. The atropia was increased to $\frac{1}{50}$ of a grain before the child was cured. Singularly to state even at this dose, although the pupils were fully dilated, he never complained of his vision or any other unpleasant symptom. Nor did any of the children that I have treated though they played out in the sunlight. I will state with regard to this case that I treated the mother for typhoid fever while she was pregnant with this child. At birth it was fairly well nourished. It was born with a cleft palate and the eyes, as the child developed, showed a want of coördination; its digestion for a bottle-fed child was good. Two nurses were necessary as one was unable to attend it on account of its sleeplessness. I rarely gave it an opiate. Bromide and paraldehyde were given with only partial relief. I then put the child on the hyperphosphate, it immediately acted like an opiate and the child was a good baby from that on.

The second child was eight years of age, a robust, healthy looking boy who had been soiling the bed for five years. He was relieved very promptly and I withdrew the medicine abruptly. The incontinence returned in a few nights and I had to recommence the treatment. The medicine was then gradually withdrawn and the cure was completed.

Reasonable View of the Case.

"Jared" exclaimed Mrs. Strongmind, "come in! You've sat out there on the front porch long enough. If you don't want to get locked out for the night you'd better move yourself!"

"My dear," expostulated Jared, mildly, "as the husband of a woman of your superior attainments and high personal worth don't you think I ought to be treated with a little more respect?"

GUAIACOL IN APPENDICITIS.

J. W. IRWIN, M. D., LOUISVILLE, KY.

On March 24th, I was called to see a girl fifteen years of age, and found her suffering from appendicitis. Her temperature was 104°.5 F. She was complaining of rigors, etc., and had been all the day before; she could not be gotten warm, extremities cold but her axillary temperature was 104°.5; and she was suffering with severe pain in the right iliac fossa, on a line with the anterior superior spinous process of the ilium about four inches toward the median line. There was one spot of tenderness at the point I have indicated, and I diagnosticated appendicitis. The next day there was a well defined tumor, about three inches in length and one and a quarter inches in diameter, extending upward and outward in the region indicated.

The patient had received the day before I saw her (she had been sick twenty-four hours when I was called) two grains of calomel, administered by the mother, and that had been followed a few hours later by a dose of castor oil. Very free purging followed the use of the castor oil, much more than the mother had anticipated. The evacuations were watery and very offensive and contained nothing but fecal matter which had a peculiar odor, very much like that of the evacuations in the latter stages of summer diarrhœa in children. The limbs could be straightened and she could lie flat on the bed without causing any increase of pain. Turning in bed to the left very materially increased the suffering, to the right it eased the pain. I felt certain that the trouble was appendicitis on my first visit. I administered paragoric and saw her again six hours later.

Temperature was still high in the axilla, and the nurse could not get her warm.

I had used guaiacol in typhoid fever, in three cases, applied over the iliac region, and thought I would make use of it in this case to see what effect it would have on the inflammatory process. I directed that fifteen drops of guaiacol should be painted over the seat of the disease, applying it over an area about the size of the palm of the hand. Cotton was applied over this and held in place with a binder. An hour or so later the temperature had fallen one degree. Whether it was from the effect of the guaiacol or a normal defervescence I was unable to determine. During the night her temperature ranged about 103° and in the morning it was 104° F. I then applied twenty drops of guaiacol over the same area without previous washing, and dressings as before. Two hours later the temperature had fallen to 99° F., and the patient was asleep. Her mother remarked to me then: "Doctor, can't I use that application oftener; soon after it was applied it relieved the pain and she fell asleep." Of course this relief may have been due to the paregoric and not to guaiacol. Anyway as the temperature was reduced the patient became very much more comfortable. The application of twenty drops of guaiacol in the morning at nine o'clock, controlled the temperature until seven in the evening, when it rose to 103°.5 F. Another application of guaiacol kept her comfortable through the entire night and the following morning until twelve o'clock. Meantime her temperature ranged between 99° and 103°. Two applications of guaiacol a day controlled the temperature, made her comfortable and relieved the pain. A drachm dose of paregoric was given at night to enable her to rest as she was somewhat nervous.

There was no sweating under the use of guaiacol, and after the reduction of the temperature, the skin remained dry. This is the seventeenth day of her illness, and there has been no elevation of temperature since the thirteenth day. The tumor has decreased in size; the tenderness has diminished under the local applications of guaiacol. Paregoric, an occasional enema, and some salicylate of quinine were the internal remedies. This with rest and a very strict liquid diet was the treatment. I think the patient will now get well without the formation of an abscess.

I saw another case this morning, in a gentleman seventy years of age. The attack is not very severe, he has been sick three days. Indications at first pointed to disease in the right iliac region and there was considerable distension of the colon, but no tumor could be discovered. There was some little doubt as to the nature of

the trouble, and he was thoroughly purged with castor oil in the beginning of the attack. His temperature was 101° F. at night, and from 99.50° to 100° F., in the morning. Pain not very severe.

This morning I saw the case for the first time; there was a large sausage-like tumor in the right iliac fossa, extending from the anterior superior spinous process of the ilium down in the direction of Poupart's ligament. Tender under pressure. The colon was distended with gas, but there was no tenderness in the region of the caecum, which we sometimes find in appendicitis. This case was diagnosticated appendicitis and as the gentleman is quite old with a feeble constitution the probabilities are that an abscess will form and the surgeon will be called in and the usual operation and autopsy will follow.

We did not apply guaiacol in this case because the temperature was not high enough to demand it, but gave him codeia one-half grain, to relieve pain and cause sleep. What the outcome of the case will be of course I do not know, nor do I know that surgical interference will be necessary. We will try to bring about a cure without resorting to surgical measures.

I have looked up the history of appendicitis recently with especial reference to the mortality in cases operated upon and those treated by the medical plan alone, and so far the result in the treatment of appendicitis medicinally is much more successful than where the operation has been resorted to. However in many cases it is probable surgery has not had a fair test. I have no doubt if many cases had been operated upon earlier they would have gotten well. In the extreme stage of the disease after general peritonitis has supervened, recovery is not so likely to follow, therefore the surgeon hardly has had what may be called a fair chance. The mortality after operations in appendicitis, so far as I have been able to collect, is about 45 per cent., while the average mortality after medical treatment is 20 to 27 per cent. The difference, however, may be due to the fact that the surgeon usually receives none but the worst cases to operate upon.

In the last twenty years I have treated at least forty cases of appendicitis; two cases a year would be a very conservative estimate. I have not had a death to occur from this cause. I have had to open abscesses and I have had abscesses to burst in various directions, and some of my patients are permanently crippled. While after the operation results have not been all we would like to see, yet when considered from every point of view, the operation must be regarded as the most rational method of treating appendicitis. The physician stands over these cases in great suspense, as he does not know at what minute perforation may take place and infiltration of the peritoneal cavity may cause general peritonitis and death. If this does not occur, he has to look forward to a recurrence of the disease, especially in the young. I am of the opinion that the time is not far distant when we will be able to reach such a point that the disease will be recognized early, the operation consented to at once, and prompt relief and cure will be obtained.

While I have not the statistics of appendicitis clearly in my mind, I believe males are more subject to the disease than females, in the proportion of 100 to 16. The age at which it is most likely to occur is between twelve and thirty-five years. It may occur in earlier life, and on the other hand, it sometimes attacks older people, as in the case I have just reported. So when I look at these cases in their different aspects, while I am inclined to be conservative, my experience leads me to make this statement, not looking at cases from the standpoint of saving life alone, I am in favor of early operative procedure, as I believe surgery will give better results than any other method of treatment. While the patient may get well without the operation, we cannot say that the disease will not occur again, and knowing this, while he is strong and no damage has been done to adjacent parts, the operation can hardly be any more fatal than exploratory incisions.

Diphtheria and Citric Acid.

Dr. H. Laser (*Hospitals-Tidende*), on account of the destructive influence which citric acid exerts on the micro-organisms of diphtheria, has adopted the following treatment in diphtheria: Each hour let the patient gargle with a dilute solution of citric acid which is prepared by addition of a tablespoonful of a 5 to 10 per cent. solution to a glass of water. Besides, have the child suck slices of lemon or drink a lemonade, which is prepared by squeezing a lemon into a glass of sweetened water.—*Lancet-Clinic.*

EDITORIAL.

PROBLEMS SCIENCE HAS NOT SOLVED.

In the President's Address, recently delivered at Oxford before the BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE, Lord Salisbury gave utterence to some words of wisdom which deserve wide circulation and thoughtful consideration. His line of thought is one familiar to every fair-minded scientist in private cogitation, but, as the speaker suggested, it did not follow the precedents usual in addresses of this character. His predecessors, in their annual addresses "had defended science when it was the object of attack, had defied theology when it was the antagonist of inquiry and investigation; and, in later years, had presented annually a bird's-eye view of the field in which they all were working." Lord Salisbury would none of these but gave a clear and able presentation of the limitations of scientific attainment as they appear to a layman who is by education, training and observation fully qualified to form an intelligent and unprejudiced judgment. His theme was "the problems science has not solved, the mysteries it has not penetrated, and the seemingly unfathomable depths its plummet has not sounded."

"The time for controversy is past; for few thinkers are now influenced by the strange idea that religious belief depends on the results of physical research. There is no longer antagonism between theology and science, because the latter has established its position. Nor was it for him to review the victories of science; rather let him set forth what seemed to a layman the fields of knowlege yet unexplored."

The address is a protest against "that mechanical theory of the universe which masquerades under the term evolution," and is a strong aggresive argument developing the conclusion that "undirected evolution is an impossible conception;" that "the argument of design has been too much overlooked," and that "the process of natural selection is only operative as it is guided by a great, directing purpose."

In working up to this main proposition —which may be regarded as the failure of science *scientifically* to demonstrate in the operations of nature, the absence of a free will, above all and controlling all—Lord Salisbury predicates :

"As scientists, we live in a small, bright oasis of knowledge surrounded on all sides

by a vast unexplored region of impenetrable mystery. The most familiar matters furnish the hardest problems. There are sixty-five substances which chemistry regards as elements, but only a third of them are used in the formation of this planet. Another third are useful, but somewhat rare. The other third are curiosities, scattered haphazard over the globe, with no apparent function but to provide occupation for the collector and the chemist. All of these elements seem to have as much relation to each other as the pebbles on a sea beach or the contents of an ancient lumber-room. How did this random collection of dissimilar materials come together? Science does not know. As little does science know of the atom, or of the mysterious ether, which we are told fills all space with its undulations. Least of all does science know life, its essence, its origin, or its operation. This is the great central mystery.

"Life is the unknown force which continues to defy not only our imitation but our scrutiny. Not only is this true of life itself, but the deepest obscurity still hangs over the origin of the infinite variety of the forms of life The Darwinian theory of natural selection is not sufficient to account for this infinite variety, and this inadequacy was never so generally recognized as now. The common ancestry of most if not all species is conceded, for since Agassiz there has been no great defender of the permanency of types. The problem is how this wide divergence of species has been accomplished. What force has been at work? What have been its methods? The Darwinian explanation has never satisfied a considerable number of scientists who are evolutionists, because at least two insuperable objections to it have never been removed. On the other hand, some of the ablest disciples of science are wholly content to explain species by natural selection. But while this wide difference of opinion exists between equally competent authorities, the problem cannot be regarded as solved.

"Lord Kelvin has never been answered since he objected, twenty years ago, 'that the amount of time required by the advocates of the theory for working out the process they had imagined could not be conceded without assuming the existence of a totally different set of natural laws from those with which we are acquainted.' The earth is not old enough, and there has not been time enough since it was possible for life to exist upon it for this divergence of species to work itself out. It is the biologist against the mathematician, the former demanding at least a hundred million years in which to cover that vast distance from the jelly-fish lying on the primeval beach to man as we know him now, and the latter refusing to grant it. The prodigious change requisite to transform the one into the other is made up of a chain of generations, each advancing by a minute variation from the form of its predecessor, and in 3,000 years the variation has not advanced by a single step perceptible to our eyes in respect to man and plants with which we are familiar. The biologists are therefore justified in demanding many hundred million years for the stupendous process. But the mathematicians measure the rate by which the earth is cooling, and deny that organic life could have existed here even one hundred millions of years ago. Between the biologists and mathematicians natural selection hangs suspended in the air.

"Weissman admits that natural selection cannot be demonstrated in detail, nor can it be easily imagined, but that it must be accepted because it 'is the only possible explanation we can conceive.' This admission puts the theory at once in the list of questionable hypotheses, and leaves wide liberty for the search for a more satisfactory one, which one finds in the old theory of design. There is no inconsistency between the doctrine of evolution

or progress by selection, and the mediate or immediate agency of a principle of design. On the contrary, the principle of design is not only wholly scientific, but the most scientific explanation of the great mystery with which he has been dealing."

In conclusion, quoting from "the greatest living master of Science among us, Lord Kelvin," Lord Salisbury finds that "overpoweringly strong proofs of intelligent and benevolent design lie around us, and if ever perplexities, whether metaphysical or scientific, turn us away from them for a time, they come back upon us with irresistible force, showing to us through Nature the influence of a free will, and teaching us that all living things depend on one everlasting Creator and Ruler."

MEDICAL EXPERTS IN DAMAGE SUITS.

In a paper by Dr. W. B. Outten, Chicago, Surgeon of the Missouri Pacific Railway, published in *The Railway Surgeon*, on the subject of "Medical Expect Testimony," Dr. Outten says:

The amount of special and peculiar knowledge or skill of the expert is to be determined by the trial judge, and he is oftentimes a very good lawyer, but a very poorly informed person in a medico-legal way. The proof demanded does not generally bear the stamp of much profundity of thought, the statement of the qualification of the expert is usually made by the expert himself. He may qualify himself by proof of his legal right to practice the profession in which he is engaged, or by showing that he is conducting a business, a wide knowledge of which he should, but may not have. To testify as an expert there, is usually no proof either offered or required as to fitness; generally the fact is accepted that the expert has been or is engaged in a business or profession which should give him the required knowledge and experience to qualify him. The question of his actual knowledge is left to be ascertained from his own answers on cross examination. And as before stated the possession of such knowledge and skill—in the medical expert—is presumed in medico-legal cases if the witness is a licensed practitioner. A legalized or licensed practitioner in our country, particularly in some western states, means merely a self-imposed or authorized prefix to a name to constitute a full-fledged physician.

I was once informed by a medical student who had failed to pass the final examination at a medical college that he was now a legal practitioner, that he had passed a satisfactory examination before a local board of examiners in a neighboring state. Upon inquiry I elicited the fact that the local or country board in the country in which he was practicing consisted of a blacksmith, a barkeeper and a justice of the peace and as our informant expressed it that there was "not much medicine in the crowd, but a good deal of muscle and whisky." Again in some states no qualification whatever is exacted, while again in others a limited period of time as an inhabitant of that state constitutes a legalized practitioner. In order to demonstrate the utter and complete inutility at times of the term "legalized practitioner" a few illustrations will not be out of place.

A passenger on a railway train by the overturning of a coach sustained severe contusions about the back extending from the shoulders to the buttocks, together with a fracture near the left wrist and a contusion of the right ankle joint. In

describing his injuries he said: "My left leg was broken, shivered I think, my left arm broken, and also my right collar bone, my back and sides bruised, and a plug cut out of my lip," and sued accordingly. Immediately after the injury he walked without assistance a distance of six hundred yards, transacted business, boarded a train and rode one hundred miles, and then drove in a wagon five miles into the country. At no time from the moment of the accident to the date of the trial was he unable to walk. He went to another state and there a doctor treated the fractured wrist with brown-paper and vinegar, which was all the medical treatment the injured man received. In the deposition of this doctor who had qualified as an expert occurs the following:—Q. "How long have you been practicing medicine?" A. "For the past thirty years." Q. "Where did you graduate?" A. "I never graduated, don't see any use in it." Q. "How many bones have we in the wrist, Doctor?" A. "Only one." Q. "What is that bone called?" A. "The nuptial bone." Q. "How many bones have we in the forearm?" A. "One." Q. "What do you call it?" A. "The meridian bone." Q. "How many bones have we in the thigh?" A. "One bone." Q. "What do you call that? A. "Call it curb bone." Q. "Are you not in error both as to the number and names of these bones. Have we not eight bones in the wrist joint, not to speak of the racius and the ulna, which form the articulation of the joint?" A. "That mought be, but during the war my books got burnt, and I hain't had any since."

Another illustration in the same case: The expert in wit perhaps, if not in knowledge in the matter in issue, who appeared to find most favor in the eyes of jury, answers as follows: Q. "Are you a surgeon?" A. "Yes, sir." Q. "Is it necessary for a surgeon to understand anatomy?" A. Yes, sir." Q. "How long is the spinal cord?" A. "I don't know." Q. "Where does it begin and where terminate?" A. "I don't know." Q. "How much does it weigh?" A. "I don't know." The attorney becoming annoyed at the nonchalance with which the doctor confessed his ignorance asked with some asperity: Does it run up and down, crosswise, diagonally, or how?" The doctor winked at the jury and answered—"I think so." The attorney, changing tactics, in the blandest tone asked: "Doctor, you claim, I believe, to be a good surgeon and a good anatomist?" A. Yes, sir. Q. "What is the flexor accesores seu massa carnei Jacopis Sylvii? The doctor said quickly "I declare I don't know unless it is an inquisitive lawyer." And still the verdict was for a good amount.

Again upon one occasion a legalized practitioner was testifying as an expert in a case where a lady passenger upon a railway train had been injured, and in the course of his examination boldly declared that a retroverted womb with existent adhesions had been caused by the accident, when it had been proven that this condition had existed some years prior to the accident. In the process of cross-examination the doctor indicated much ignorance and confusion as regards his views of versions and flexions of the womb, and finally asked in what condition he found the lady's prostate gland. He very gravely answered that it had not fallen yet, but there were very serious doubts about its remaining in its normal position. Thus it may seen that while a qualified practitioner under law constitutes an essential basis of the expert yet in reality it oftentimes is the reverse.

It is a fact noted not only by attorneys of experience but by others attendant upon court that experts are more frequently selected not because they are especially well qualified or most competent to form a correct judgment but because their opinions are known to be favorable to the cause of the litigant at whose instance they appear in court. It is unfortunate, but the natural trend of most men is in the direction of partisanship, and equally unfortunate that the medical expert is very rarely surperior to this trait. In fact it comes very near to being characteristic, and in our experience specialties in medicine seem to strangely influence this course. The testimony of an expert is for the most part not given from the witness' own examination and estimate of the material fact but upon hypothetical cases which are supposed to embody the facts in evidence in the cause, but which confessedly may not embody all the facts material to the formation of a correct judgment. The hypothetical case is framed by one versed in law, and not medicine is built upon a theory in law, and as before stated oftentimes but poorly represents the true issue in fact.—*Railway A*

THE PHYSICAL BASIS OF KNOWLEDGE.

The surface of the brain has many centers upon it, whose functions have been carefully studied. In addition to these centers, there are tracts of nerve matter connecting them with each other, so that associated or concerted acting of the brain centers becomes possible—indeed, is of constant occurrence. One hears the word "rose" spoken, and immediately the image of a rose is recalled; there is a recollection of its odor, of its color, of its size and shape, and a stimulus goes to the proper center, so that the word "rose" may be spoken or written, if it is so willed. It is these tracts or paths of nerve matter that enable the bran to build up our complex ideas. It will be seen from what has been said that the word "rose" carries with it many elements, such as color and shape, learned by experience through the eyes; taste, by the tongue; odor, by the nose; weight, by the hands. But all these qualities of taste, color, odor, weight, etc., go to make up our complex idea of what a rose is. These varied primary or elemental ideas have reached the brain by separate channels, have formed memory pictures on the centers, which, in turn have become associated by means of the inter-central nerve paths into complex ideas.

In addition to the impressions reaching the brain through the nerves of hearing, sight, taste and olfaction, there is a constant stream of sensations pouring into the brain along the nerves of feeling. It has now been pretty well settled that some of the nerve fibres conduct sensations of heat, others of cold, some of pain and still others that sensation known as muscular effort, or the muscular sense. All these are carried to different parts of the brain and there registered. From this registry, they can be called up as a memory of past experiences. It will now be clear that there a constant stream of sensory currents or sensations coming into the brain from all parts of our bodies. These sensations have their mental accompaniment. When a current escapes from the brain, and goes outward for the purpose of moving some muscle or group of muscles there is also a mental accompaniment. It is in this way that we are aware of how we are acting and being acted upon. These constitute states of consciousness. The conscious personality, or conscious ego, is the sum of all the states of consciousness at one time existing.

In a moment, by disease or injury, a man may lose the power to speak, and yet be able to read and write; or he may be unable to read, and yet hear what is said. Some may have the center of hearing so damaged that the power for music is gone and still be sound in every other respect. Some, again, may lose the power of recalling words. They know them when written or printed; but they cannot speak, because they cannot recall the words needed to express their thoughts. Enough has been said to show that the brain and all the nerve tracts leading to it and from it are the physical basis of knowledge. Derangement in these is followed by derangement in the mental powers. Insanity is only diverse, affecting the brain so as to derange and pervert the thoughts, language and actions of the person. This view of insanity has done much good, as it has led to a better method of dealing with insane people. The anatomical and physiological study of the brain shows that it is the organ of the mind; but further observations made in cases of disease and injury of the brain as well as on cases of insanity, go to establish this doctrine beyond all dispute. Illusions, hallucinations and delusions owe their origin to some derangement in the sense organs or in the perceptive centers in the brain. Following upon this, the conscious ego is no longer in its true relationship to its environments, and there is, as a consequence, derangement of conduct, as the result of the physical disease.—*Canadian Mag.*

Benzoate of Sodium.

The combination of borate of soda and benzoic acid is extremely beneficial in various forms of kidney and bladder difficulty. Perhaps the most advantageous results are obtained when there is an excess of insoluble urates or of uric acid; the urates are at once converted into soluble, harmless, easily eliminated hippurates.

In high specific gravity of the urine, excessive urea in lithæmia, in lithæmic albuminuria, and renal hyperæmia resulting from these conditions, the mixture is exceedingly serviceable.

NOISES IN THE HEAD AND EARS.

Dr. Barclay, Aural Surgeon to the St. Louis Baptist Hospital, in the *Hospital Bulletin*, (May, 1894,) writes:—The question is frequently asked "What are 'Noises in the Head and Ears' and what is their signification?"

A satisfactory answer can perhaps be deduced from the following discussion;

Aerial sound-waves, reaching the healthy ear with sufficient force, impart that force to the movable tissues lying between the outer air and the auditory nerve filaments in the labyrinth where tissue vibrations are transformed into nervous stimuli, these stimuli being thence conveyed to the auditory centre in the brain, where they are interpreted, by consciousness, as sound.

The movable tissues spoken of above, by whose operation the force of aerial sound-waves is transmitted to the terminal filaments of the auditory nerve, constitute an apparatus which is generally termed the "transmitting-mechanism" of the ear. This transmitting-mechanism moves, if at all, as a solid body, in response to the impact of sound-waves; and may therefore, so far as its obedience to the force of sound-waves is concerned, be considered a mechanical unit, a vibratory lever, as it were. This vibratory lever, so to speak, is, normally, so nicely adjusted and related to the parts with which it is in contract or connected, that, however numerous and complicated its attachments, contacts, or connections, however complex its pivot or fulcrum, mechanically, and whatever the nature of its equilibrium, it may be looked upon as constituting with other parts a balance whose tension with those parts preserves a certain equilibrium. Now the transmitting mechanism of the ear is so constructed that aerial sound-waves act more directly and more effectively upon one end of this balance than upon the other, thus disturbing the relation between all parts of the transmitting-mechanism and the other portion of the balance—moving the balance upon its pivot, as it were, and the fluid in the labyrinth, thus disturbing the terminal filaments of the auditory nerve (which are at rest when the balance is at rest), and inducing a sensation of sound at the auditory centre.

On the other hand, tissue sound-waves, generated within the head in performance of the physiological fnnctions of phonation, respiration, circulation, mastication and deglutition, or transferred to the head by contact with musical instruments, tuning-forks, etc., act upon the healthy ear as force exerted upon the fulcrum only, or, simultaneously, upon all parts of a balance, producing but little if any disturbance of the balance as such, nor disturbing the relation hitherto existing between the transmitting-mechanism and the contiguous parts in the labyrinth, but pass out over the bridge of ossicles and drum-head as force is transmitted through a straight line of touching billiard-balls, without their appreciable disturbance, to be discharged at the last ball.

If however the exit of such sound-waves is obstructed by any condition of a mechanical nature, the waves rebound with a force proportional to the degree of obstruction; and disturb the relation between the deeper-lying parts of the transmitting-mechanism and the tissues enclosing them, displacing the auditory nerve filaments and inducing a sensation of sound.

It should be borne in mind that the presence of any adventitious substance in the auditory canal—whether excess of cerumen, a verruca, exostosis, wad of cotton, "foreign body" or what-not—will, so far as it obstruct the exit of sound-waves, cause them to rebound, with force frequently sufficient to drive the echo back again through the tansmittiug-mechanism to the nervous apparatus. If the lumen of the canal be closely stopped with the finger, cerumen, or other obstacle, the echo is rendered more forcible, not only by the completness of the barrier from which it has rebounded, but through reinforcement from the drum-head, which acts as an additional barrier in that its excursion is abridged by the compression of the air shut up in the auditory canal. The same thing obtains where the tympanum contains liquid; when the Lumen Eustachian tube is obstructed or closed; or when other conditions exist, preventing excursion of the drum-head to a normally accommodating degree. When the foreign-body, cerumen, or other substance, rests directly against the drum-head, the ex cursion of the membrane is still more

effectually prevented, and the echo is the more forcible.

Whatever condition arises to disturb the normal equilibrium, the balance, as it were, of tension between the transmitting-mechanism and the parts with which it is in contact or connected, will more or less bind down one end of the balance, change the position of the fulcrum relative to the lever, so to speak, and render less effective sound-waves from without, more effective those from within the tissues of the head, in their operation upon the terminal filaments of the auditory nerve.

The signification of Noises in the Head and Ears, then, is that of a disturbance of the normal equilibrium or balance of tension between the aural transmitting-mechanism and the parts with which it is in contact or connected.

HYPODERMIC INJECTIONS OF STRYCHNINE AND ATROPINE IN THE LIQUOR HABIT.

Dr. G. W. Bath, of Ohio, Ill, in the *Clinique*, says:—Two years ago I began giving treatmnet for the Liquor Habit. I reported 8 cases in the fall of '92. Since then I have had several letters from different parts of the country making inquiries about the treatment and the patients. It is with a view of answering these inquiries as well as making a final report that I write this paper.

The patients are all residents of this town and vicinity; so I have been able to see them nearly every day since they took treatment.

Concerning the efficacy of the treatment, I have this to say;—that it is a cure so far as the treatment of any disease is a cure. Indeed I think it just as sure as a surgical operation or the treatment of malaria or syphilis. Strychnine is the drug upon which I rely.

The form commonly used is the tablets of the nitrate one-fortieth gr. The strychnine is combined with atropine sulphate in quantities to suit; beginning with an injection of one-fortieth gr. of strychnine and from one two-hundredth to one one-hundred and fiftieth gr. of atropine; using the injections from two to four times per diem, according as the patient requires, and increasing the strychnine during the first week, until by the beginning of the second week the patient receives from one-eighth to one-fourth gr. each day.

The atropine is likewise increased to its full physiological extent, producing the dryness of the mouth and fauces and blurred vision. It is well to bear in mind that strychnine can be tolerated to a remarkable degree as reports on the treatment of asthma and various neuroses show. At the end of the second week the doses must be decreased until the end is reached with about what was originally given.

After two to four days if the patient is drinking his desire for liquor will cease. Drinking and food taste badly. This is undoubtedly due to the fact that the secretions are charged with the drugs: some nausea will likely be experienced even to the extent of vomiting, especially if the patient persists in drinking. The atropine is liable to cause nausea when giving freely. Yet contrary to some authorities I think the strychnine capable sometimes of doing the same. In experiments with strychnine which I conducted upon myself, I found that when I attempted to move about the limbs stiffened; I felt my heart beats decidedly strengthen and had that sea-sick smile termed the "risus sardonicus" but I became violently nauseated and vomited several times. I am told that at the "institutes" if the patient persists in drinking beyond 3 or 4 days and still craves it, he is given an injection called the "barber pole" because of the various colored liquids used in its composition. He is then handed a big drink and is told to go out and sit down. In a few minutes he feels that certain products will likely have a rise. He is not mistaken either, for up it comes. The "barber-pole" is nothing more or less than apomorphine which being a systemic and prompt emetic makes the patient believe that he can no longer bear whisky so he usually, after that, leaves it alone. I have never had occasion to use the apomorphine in this connection, finding that plenty of strychnine and atropine does the work.

The injections should be continued over a period of at least three weeks, during

which time the patient will have received from forty-five to ninety injections. It is well to give as an aid to the hypodermic treatment some tonic mixture as nux vomica, digitalis with tincture of capsicum, if necessary; or some of the ordinary bitter tonics might answer, the entire idea of the treatment being to keep the system thoroughly saturated with the drugs, using such agents as best favor reconstruction of the nerve tissue and the elimination of the waste products. I consider atropine an eliminant of considerable virtue. By contracting the arterioles and thus increasing the blood pressure, the quantity of urine voided is much larger. The tonic action of strychnine upon the unstriped muscular fiber causes increased peristalsis and copious evacuations of the bowels result—although atropine alone when given for a period causes an increase of the stool.

Concerning the best time to treat the patients: I fancy the results have been more prompt when the patient has been drinking freely. I usually allow the patient to drink until he is tired of it. He generally quits of his own accord. But if one found it necessary an injection of the apomorphine could be used, to produce the impression that liquor was no longer borne and would vomit the patient if it were taken. Now, to speak of the results with my patients. It has been all any one could ask. I have treated three others aside from those named in the article referred to with the same satisfactory results. The second case given as D. H., took to drinking in about four months after treatment although thoroughly cured. He was like the poor dog Tray, who fell into bad company. His old chums actually poured liquor down him. The poor fellow was beset with all manner of temptations and finally succumbed to the old habit.

I am reliably told that he made poor business of it. That the whiskey made him quite sick. I am happy to add that within the last week he has resolved to give himself another chance and live a sober life, and I have begun the treatment for the second time with him. All the other cases except one have remained "cured." They enjoy good health, are successful in business, have neither become crazy nor impotent. Although daily were drink can be had, they say they have no desire for it.

In conclusion the most important point is the

MORAL.

My experience has been somewhat dearly bought. In this little town with three saloons I have encurred the enmity of the saloon men and their friends. One case which I foolishly undertook to treat about one year ago, was of a man who was the most complete specimen of a drunkard I ever saw. For several years he had never drawn a sober breath. He had all the advanced symptons of total inebriety; swollen skin, yellow conjunctiva, shambling gait, loss of memory, incoördinate speech and gastric catarrh. Besides, he had suffered from delirium tremens frequently. In such a state was he when I undertook his case. I began his treatment on Saturday night and by the following Monday night he had no further use of my service—in plain words he was *dead*. He died in one of the worst spells of delirium I ever saw. I had given this patient but three injections of one-eightieth gr. strychnine each. But it became a favorite fling of the "bummer class" that I had killed him, and the news of his death was carried from Dan to Bersheba. The moral from that case was always to inform the family that no risk will be assumed; and then if the patient dies during the treatment one incurs no responsibility. But wiser still I think it very risky when one is so far gone to ever attempt the case. One will be better off in every respect without such patients.

Another thing is the social standing of the patient. If the patient is a man of a family the chances for his continuance are much better. It is known that a great per cent. of drinkers are started in their career through lack of proper associations. They become accustomed to resort to the saloon to loaf and chat, and from that the road to drunkenness and vice is not difficult. So a great menace to the success of the treatment of the patient is, what can be done for him after he is reformed? A man must have more than ordinary stamina to reform his social life after he is cured of drink. Hence the great number of those who go back to their cups are those whose only acquaintances are old chums of the bowl. In

their reformed state they are like Robinson Cruso on his island; and rather than endure this social isolation and taunts of their old companions they go back to drinking again.

Still another point necessary to bear in mind. It is necessary to impress upon the patient that a hypodermic injection will not make a reformation in him unless he is willing to help himself. He must be positively forbidden to lounge about the saloons simply that he may know whether or not his appetite is gone. Too many people expect to have somewhat of a miraculous nature in it. Not so at all. A man can certainly acquire a taste for drink in spite of the treatment if he persists in trying. The physician should also never attempt to treat a patient without his fullest consent and coöperation. If simply at the solicitation of his friends one treats him without his knowing what the treatment is for, the chance is good for a grand failure. The patient must realize that if he is to take treatment it must be a matter of sufficient importance to him that he be completely under control. No hop, skip and jump matter, but one of serious business.

So much for the treatment.

But the physician's place should not simply be that of curing the drunkard. He should take stand as a public educator on the evil influence of alcohol. I say it without fear of contradiction that in the great majority of instances where liquors are prescribed, the patient would be much better off without them, and the physician would not be considered in the class of those "fellows who prescribed a little brandy for this complaint and a little beer for that." As a scientific man he should be above such shallow quackery and lend his aid to putting down this gigantic evil which largely underlies many of the moral corruptions of all lands. When scientific men get somewhat over the microbe craze they will still find sufficient work to expend their energies upon in trying to save our nation from the 100,000 deaths annually occurring through strong drink.

SOCIETY REPORTS.

THE LOUISVILLE CLINICAL SOCIETY.

April 10, 1894.

[STENOGRAPHICALLY REPORTED BY C. C. MAPES.]

POLYPUS OF LUSCHKA'S TONSIL.

DR. WM. CHEATHAM: This specimen was shown at the Surgical Society last night, and I only present it before this Society because in an examination of the patient to-day I have discovered that it is a rather unusual growth, or springing from an unusual locality. When I removed the growth yesterday I supposed it sprang from one of the turbinated bones, hanging down from the post-nasal space into the pharynx—a mucous polyp, but the bleeding was so free that I could not discover its exact origin at the time of removal. In making another examination of the patient to-day I found that the growth had its origin in what is known as Luschka's tonsil, left side. In looking over McKenzie's work I find he refers to only two cases of pedunculated growths of the pharynx. That being the case it makes this polyp springing from that location very rare. It had undergone cystic degeneration; of course it collapsed as soon as punctured and is now only about one-third the size it presented when removed. This patient came from the country and gave the history of a peculiar sensation in the throat; that whenever she attempted to swallow it felt like she "was swallowing her own head." Soft mucous polypi of the post-nasal space originating in the nose are not very unusual; in their removal not much local anaesthesia is necessary, as the pressure of the growth produces a condition of semi-anæsthesia of the parts, so that traction can be made on the soft palate and the growth can be removed by the use of a very little cocaine. This growth was removed in the following manner: A weak solution of cocaine was sprayed into the

left nostril for anæsthesia and to shrink the turbinated tissue to enable me to pass a soft catheter through the nostril and out of the mouth, to tie the soft palate forward; to the end of the catheter I tied a string—silk thread—passing it through the nose and out of the mouth. After getting it through the nose and mouth, I cut the thread from the end of the catheter and tied the catheter firmly over the upper lip. I then took a Douglas snare with wire in canula and attached the end of the string which was in the nose to the loop of wire and pulled the wire and canula through the nose, and the loop into the post-nasal space and pharynx. With a velsellum the polyp was drawn through the loop, the polyp having undergone cystic degeneration, ruptured; in endeavoring to tighten the wire around the growth, the latter came loose. The snare I used and which I exhibit here, is one of the best for such operations, I know of. You will observe that the heavy handle can be detached and reattached with no trouble. Should the growth to be removed have undergone fibroid degeneration, thus making the operation more difficult, and increasing the danger of hemorrhage, it is of much more consequence, especially when the cold wire is used, to cut slow, to rest the patient often, and thus to avoid hemorrhage. While your patient is resting this heavy handle can be removed and easily reattached when you wish to continue the operation; with this screw as much force can be applied as with any snare. As I before stated the screw did not have to be used, not even the handle attached; when the growth came away, hemorrhage was not great, but enough to interfere with good visual inspection, and as the patient was much wearied I made no further examination that day. The next day I located the origin of the growth, as I stated before, from the left side of the pharyngeal tonsil; the stump was cauterized with chronic acid. While on the floor I wish to refer to the soft rubber catheter as a means of plugging the post nose. Still better is a small copper wire as shown here. This will go through noses through which the catheter will not pass. It is also cleaner and can be thrown away after using once. However, nasal plugging is but seldom necessary now. The bleeding point is usually on the anterior half of septum, and can be usually seen and cauterized.

DISCUSSION

DR. J. W. IRWIN: I was very much interested in Dr. Cheatham's account of removal of the nasal polyp, but more especially in regard to his statement that it is not necessary any longer to plug the nose in epistaxis. I wish particularly to ask the doctor what to do in some cases that come under the observation of the general practitioner, in inebriates, in bleeders, in those suffering from malaria-hemorrhagica, and disorders which terminate speedily in death unless some measure of this kind can be instituted, until constitutional remedies take effect. I have had the misfortune to see three deaths occur from epistaxis, two in inebriates and one in a bleeder, and also came very near losing four cases of malarial hemorrhage from the nose, and believe that death would have occurred if it had not been for plugging the posterior nares. I certainly would have lost one case because I could not get the patient early under the effect of quinine. In such cases I would like to know if Dr. Cheatham will suggest a remedy that would do away with the necessity of plugging the nares, and making the patient feel very uncomfortable?

DR. WM. CHEATHAM: In answer to Dr. Irwin's question: In a large majority if not all these cases, the bleeding is from the septum and not from the turbinated bones as stated by the older authorities.

In a large majority of cases you can wash out the nose, locate the bleeding point and cauterize it. I remember a case not long ago occurring in the practice of another physician where a lady had excessive nasal hemorrhage and the physician had plugged both the anterior and posterior nares. I removed all the plugs, thoroughly washed out the nose, located the bleeding point on the septum, and with a pair of ciliary forceps which I happened to have in my pocket, I attached a piece of cork to each blade of the forceps and passed one blade in each nostril put one piece of cork against the bleeding point, took a strong cord and passed it around the blades of the forceps bringing them firmly together, and the patient had no further hemorrhage. Nasal breathing was not interfered with at all, as these pieces of cork did not obstruct the passage, and the patient was much more comfortable than with both the posterior and anterior nares plugged. The danger of sepsis is also very great from plugging

the nose, in fact we know it is almost impossible to prevent sepsis about the nose. It is necessary to exercise the greatest possible care in all surgical operations about the nose to prevent sepsis. In plugging the nose we have a quantity of decomposing blood which is very dangerous, and the method I have spoken of certainly is much more safe and more comfortable than plugging. On account of the susceptibility of the nose to sepsis, nasal diphtheria is more dangerous than that affecting the pharynx; in some such cases as those to which Dr. Irwin refers, plugging may be necessary, but not many.

In every case of nose bleeding I examine the heart, kidneys and liver.

Dr. T. P. Satterwhite read a paper on

INCONTINENCE OF URINE IN CHILDREN, TREATED WITH ATROPIA.

(See page 322.)

DISCUSSION.

DR. J. M. KRIM: I have a case under observation now that has been suffering with chorea and incontinence of urine for some time. The patient is a little boy ten years of age. In an examination I found he had phimosis. As soon as he was relieved of the phimosis I expected the incontinence of urine and chorea would cease, but they failed to do so. I put him on atropia, starting with $\frac{1}{100}$ grain. After three weeks treatment the incontinence and chorea disappeared. Phimosis is frequently a factor in the production of chorea, and usually ceases when the phimosis has been relieved, but in this case the chorea continued for three weeks after the condition of phimosis had been relieved.

DR. J. W. IRWIN: I wish to commend the paper in detail; it is a very explicit statement of a condition frequently met with by all physicians doing a general practice. Certainly everything has been made plain by the essayist, and the paper could hardly be improved upon in a general sense. The causes of nocturnal incontinence of urine have been carefully enumerated, and I have no doubt in many instances many of them conduce to the trouble of bed-wetting. But my experience goes a little beyond the local cause of this trouble. I have found most children who wet the bed usually of tubercular, or scrofulous diathesis, or they have a nervous predisposition. They have some history showing a departure from the standard of health as a rule. It is a rare thing to find a child who is robust and healthy in every respect to wet the bed persistently, but now and then a child will do so even when apparently in perfect health. When children overload the stomach, take excessive exercise, and become so profoundly tired that the call of nature is not sufficent to awaken them they wet the bed. Many cases can be accounted for in this way, in healthy children, who require no treatment beyond correcting the errors in diet or exercise.

The essayist spoke of the remedies employed in the treatment of this troublesome disorder and laid a great deal of stress upon the use of atropia. I believe that atropia as a single remedy is perhaps the best of all, but it is by no means a panacea. Instead of finding the urine acid in reaction, as stated by the essayist, I have frequently found it alkaline. I have often encountered children suffering from nocturnal incontinence of urine with cold extremities, cold skin, feeble circulation and a sluggish atonic condition of the whole body. In such cases I have found great relief to often follow the use of a solution of phosphorus—dilute phosphoric acid—three times per day as a constitutional remedy. In others I have found the tincture chlor. of iron to be most serviceable and it often gave permanent relief. I usually administer a dose of atropia at night and direct that as small a quantity of water be taken at bed hour as possible. I think phosphorus is a valuable remedy in many of the cases—the essayist also touched upon the use of this remedy—very frequently it has the effect of producing a complete cure. Quinine is also useful, especially tannated quinine. I believe this form of quinine to be the next best remedy to atropia, but it should be long continued and given in moderate doses. For a child two years of age two grains of tannated quinine three times a day would not be too much, and it should be continued at least, for thirty days. When a child is six, eight, or ten years of age and still wets the bed, I have found an excellent remedy in the Faradic current applied one pole (positive) to the nape of the neck,

the other (negative) to the perineum. An application of this agent twice or thrice weekly does much good, and is often more effectual than atropia. Another thing we must not lose sight of in giving atropia, is the enormous doses that a child can bear; a child may be given much larger doses of atropia in proportion to its age, than the adult, without producing a poisonous effect. I believe we often give too little atropia in treating children for incontinence of urine; to a child two years of age I have given $\frac{1}{60}$ grain at night without bad results. This is a larger dose than is usually given to the adult.

DR. P. F. BARBOUR: The subject under discussion is especially interesting to me, as I have seen a great deal of incontinence of urine in my clinical experience, and in private practice also. Like the gentlemen who have already spoken I think atropia is probably the best remedy in these cases. The first thing to do in the case is to ascertain the cause of the incontinence, and this very frequently is the most difficult part of the treatment. Dr. Satterwhite has mentioned most of the causes that are believed to be factors in producing incontinence. In my experience phimosis has been the cause of more cases of incontinence of urine than any other one condition. I have found in some cases where there was only partial phimosis, the inability to retract the prepuce completely set up a sufficient nervous irritation to produce this trouble at night. In fact I have had one or two cases where I failed to produce a perfect retraction on the prepuce and atropia had no effect; after I had secured perfect retraction, combined with atropia, the child rapidly improved. Of course, cystitis, irritation about the bowels, rectum, or in fact any part of the gastro-intestinal canal, or a reflex from any point in the whole system, is liable to produce incontinence of urine. The doses of atropia reccommended by the essayist are not too large by any means. Children can bear two or three times as much of this drug in proportion to their age, as an adult, and I have usually given very large doses even at the beginning of the treatment. I have prescribed for instance in solution one grain of atropia to an ounce of water, giving at a dose as many drops as the child is years old though I rarely exceed five drops as an initial dose. Cantharides is indicated in some of these cases, where there is atony of the sphincter muscles of the neck of the bladder. When it is not due to lack of nervous control but to atony of the muscles, as Dr. Irwin has said, the Faradic current is an excellent treatment. The action of belladonna I have not found so reliable as atropia.

DR. P. GUNTERMAN: I agree with Dr. Satterwhite as to the necessity of looking into the condition of the general health, and that this must be brought up to the normal standard before atropia or any other remedy directed to the relief of enuresis can be of any benefit. I do not agree with Dr. Irwin that the majority of the children who suffer from incontinence of urine are either of strumous diathesis, nervous temperament or scrofulous habit. I have treated quite a number of children for this trouble, and the patients I have had, particularly the last five treated during the past year, were of very healthy parentage, were themselves apparently very healthy children, with perhaps one exception, and certainly had no strumous or scrofulous taint. These five cases made a very prompt recovery under the atropia treatment. My mode of treatment was the same as that of the originator of the method, viz.: I gave one drop for every year of the patient's age of the solution of one grain of atropia to an ounce of distilled water, which in the oldest child made $\frac{1}{60}$ grain, and in the youngest $\frac{1}{240}$ grain to begin with. This was continued twice per day—in the afternoon at 4 o'clock and at 10 o'clock at night. This treatment was kept up as a rule about six weeks. One case, a boy seven years old, was relieved in four weeks, then the mother thought as the boy could not see very well and had some general constitutional disturbance, that the medicine had been continued long enough and quit. In about two weeks the treatment was again instituted and continued another four weeks when the boy was entirely cured. I had another little patient four years old, rather weak and delicate. He wet the bed at night—in fact was always wet. I gave him a constitutional treatment consisting of tincture of iron and corrected his urine. I gave him cantharadine—one-fiftieth of a grain three times a day—and before I knew it he had as bad a case of cystitis as I ever saw. It seemed as if he passed the whole of the mucous mem-

brane of the bladder within twenty-four hours. The little fellow recovered from that, but the incontinence was not relieved until I put him on atropia, starting with four drops ($\frac{1}{100}$ part of a grain) twice per day. He made a very steady improvement, kept on improving and finally became entirely well and is well now.

DR. T. P. SATTERWHITE: I think it is necessary to give atropia oftener than Dr. Guntermann states; it is eliminated very rapidly and twice per day is not sufficient. In all my cases I gave it three times a day and kept up the remedy at least a week or ten days after apparent cure. I did not withdraw it at once, but decreased the dose gradually.

ACCIDENT FROM THE USE OF BROMOFORM IN PERTUSSIS.

DR. P. GUNTERMANN: I wish to speak of a peculiar accident I had last Friday evening. I had prescribed for three children in the same family; one aet. 1½ years, one aet. three years and one not quite five; mixture of bromoform two drams to four ounces of syrup of tolu to be given, 60 drops to the oldest, 30 drops to the second, and 10 drops to the youngest child. All were suffering from pertussis. They took the medicine and I was to be advised how it acted when the supply was exhausted, or sooner if it did not act at all. I learned how it acted when the last dose was given. I was called at 7 o'clock in the evening to come at once, as one of the children was dying. When I reached the house I found that the child was perfectly dead drunk. I thought at first that the child had had a spasm and was simply limp from its effects; there was nothing to indicate any serious danger, and the child had gone to sleep. I told the family to let the child sleep, and if they saw anything out of the way to let me know. A half an hour later I was called again and found the second child unconscious and perfectly limber, having no control of the muscles whatsoever. In another half hour the oldest child was taken in the same way. The pulse of each was good, they were quiet, breathing was natural, pupils looked all right, so I inquired whether they had anything about the house that might have been taken by mistake. Investigation revealed that the only medicine they had taken was the bromoform and syrup of tolu which I had prescribed, which I knew could do them no harm. I found they had taken the last of the medicine that evening, and the mother said: "Doctor, there is something peculiar about that medicine; when you do not shake it there is always a lot of oil in the bottom." I knew then what the trouble was. They had not shaken the medicine and had taken pure bromoform, the last dose left in the bottle.

ATRESIA VAGINÆ.

DR. W. H. WATHEM: Four weeks ago I operated upon a married lady from Louisiana for atresia vaginæ of the upper half, the lower half being normal. By an examination through the rectum and bladder it was impossible to decide positively whether there was congenital absence of the upper part of the vagina, or whether there was simple atresia resulting from inflammation, with atrophy and thinning of the walls. The uterus was normal in size, and the ovaries and tubes apparently normal. She was perfectly developed in other respects, a bright, intelligent and accomplished woman. Her menstrual periods had been regular, though very painful and prolonged. I found fistulous opening through which I could introduce only the smallest probe, entering the vagina on the left side and through this menstrual discharge came away. A small uterine dilator was forced into this opening, and the blades spread making an opening large enough to introduce my finger. With the handle of a scalpel the united surfaces at the upper part of the vagina were divided, and then with my finger I began dissecting above, and discovered that I was not separating an adherent vagina but was separating through connective tissue uniting the bladder with the rectum, showing that there was congenital absence of the upper half of the vagina. I finally reached the uterus and continued dissecting through the connective tissue until I had opened into Douglas' pouch. This allowed the uterus to come lower in the pelvis between the rectum and bladder, and bring the os uteri near the vaginal tissue proper. There was but little hemorrhage, and the cavity was tamponed gently with iodoform gauze. She had no untoward symptoms; no eleva-

tion of temperature nor acceleration of pulse; she suffered no pain—absolutely in a normal condition; the dressings were changed every two days; the peritoneal wound healed completely, and the mouth of the uterus was down nearly to the vagina. She menstruated while at the Infirmary and had no pain; the flow lasted about half as long as had been customary before the operation. She left the Infirmary two weeks after the operation with the cervix firmly fixed, the os large enough to allow the introduction of end of my finger, and she was in every way feeling perfectly well. Had I not opened the peritoneal cavity the uterus would probably not have come down lower than it was, and the separated space between the bladder and rectum would have retracted until possibly there would have finally been but a small fistulous opening and the woman would have suffered with painful menstruation as in the past. But by separating into the peritoneal cavity allowing the uterus to come down it will do away permanently with any trouble in menstruation. But there is a question about which I have serious doubts in this case, viz: the ability of this woman to give birth to a child through the vagina, because the uterus is not attached to the vagina; it is attached only in front to the bladder, behind to the rectum, and at the sides to the connective tissue of the pelvis and the broad ligaments. I believe that were she to go into labor at term there would be danger of serious injury; the uterus when contracting and pressing the child outward would, because of feeble vaginal attachments, cause the cervix to become torn from the pelvic structures and allow the child to pass into the peritoneal cavity necessitating an abdominal section. With this belief I advised against her becoming pregnant, and told her husband the dangers such a condition might entail.

I have had two cases of total congenital absence of the vagina—one in a lady living in the southern part of the state, who is otherwise perfectly developed, breasts, vulva, etc., and having all the feelings of a perfect woman in relation to the opposite sex, neither vagina or uterus could be detected, although it is claimed by some authorities that there is always some of the uterus present in these cases, but it is very small. Her ovaries and tubes could be distinctly outlined.

The other case is a little girl of a prominent family in this city, where there is entire congenital absence of the vagina with the presence of the ovaries and a very diminutive uterus. As the child is but four years of age, and as the uterus is at this age very small, when she develops into womanhood it may develop sufficiently for menstruation which will have no outlet.

I report these cases because they are not of usual occurrence, many busy physicians may practice for many years and not see such a case. I have seen but these three cases. It is not a very uncommon thing to see acquired atresia of vagina resulting from specific infection, from infection following childbirth, from infection of measles, small-pox or even diphtheria, and one reason why I thought the last case upon whom I operated was acquired adherent vagina was because her husband told me that when she was eight years old she suffered with a severe attack of diphtheria, and had some vaginal discharge. The vagina, uterus and tubes are developed from the ducts of the Müller, from above downward. We may have absence of the upper, middle or lower part of the vagina, but we very seldom have absence of the middle of the vagina with the upper and lower parts existing, and as a rule we have either entire absence of the vagina, or only the upper and lower part. The vagina may be absent and the uterus fully developed, or the vagina may be absent and the uterus apparently absent. With entire absence of the vagina, with the presence of the uterus and ovaries well developed, the better treatment would be to remove both the uterus and the ovaries, as they could be of no use to the woman and might cause her a great deal of pain and suffering or even death. If you were to attempt to establish vagina in a case of this kind, you would have great difficulty in reaching the uterus and opening the parts well without danger of injuring the rectum and bladder, especially so if the union of these two organs happened to be such as to require any instrument except the fingers in separating them. When an opening is made, contraction will gradually take place until you will have practically nothing better than a fistulous opening. In acquired atresia, of course, we may by operation in many instances re-estabish the vagina.

CURRENT LITERATURE REVIEWED.

IN CHARGE OF ELLISTON J. MORRIS, M. D., AND SAMUEL M. WILSON, M. D.

THE ANNALS OF GYNÆOLOGY AND PÆDIATRY for July. Dr. Thomas D. Dunn reports

A Probable Case of Auto-Infection,

with some remarks on the bacteriological origin of puerperal sepsis. In the case reported by the author there was no laceration of the birth canal; the placenta was delivered spontaneously and was apparently entire. The patient complained of great weakness, pain and uterine soreness out of all proportion to the severity of the labor. The uterus did not contract firmly. Eleven hours after delivery the author was summuned, and found a temperature of 104°.6 F., pulse 112, great restlessness and considerable pain. The uterus was large, but no blood clots had passed. The patient then developed a typical case of septic infection and died on the tenth day of the disease. On the sixth day she complained of pain in several joints, and on the seventh both wrists, right elbow and knee were painful to motion and pressure, red, and on the eighth day large fluctuating abscesses were present. There were no rigors, but the temperature and pulse continued high till death. Uterine soreness ceased on the second day, but at no time were there firm contractions. On the sixth day the woman was etherized and the uterus carefully explored and curetted, with the removal of some debris—either fragments of placenta or a sloughing ulcer—the latter sensation being given to the finger.

The child was not nursed, owing to the severe illness of the mother. On the first day it was exceedingly fretful; on the second day it refused nourishment and had high fever, temperature 103° F. On the third day the right elbow was swollen and red. Septic arthritis rapidly developed, and on the fourth day left elbow, both wrists, ankles, and left knee were involved. Several abscesses were opened and discharged a sero sanguineous pus. The child died on the sixth day.

No post mortem was allowed to be held on the patient or could any bacteriological study be made of the lochial discharges.

The attendant being called away from the city, a visit was made by his brother five hours before the patient was delivered. The brother had come directly from a case of diphtheria, but had washed his hands with antiseptic soap, and unusual vigilance was used to sterilize the birth canal both before and after delivery. It was carefully examined by speculum, but at no time could evidence of diphtheritic deposit be found. The author is inclined to consider the case one of auto-infection on account of the condition of the child; as he thinks it impossible that the child could have become infected if any poison had been placed in the birth canal five hours before delivery.

Dr. Rufus B. Hall contributes some remarks on

Total Extirpation of the Fibroid Uterus,

describing illustrative cases. The author prefers total extirpation to Baer's method of extirpating the tumor and body of the uterus, leaving the cervix. He is opposed to the extra-peritoneal method by means of the nœud. He believes that with the present rate of low mortality following total extirpation of the fibroid uterus, we should not hesitate to advise all patients who are subjects of fibroid tumor to submit to the operation at once if their life is endangered or health destroyed either from the tumor or complications arising from it.

This issue also contains the abstract of a paper by Dr. Edward P. Davis, read before the American Gynæcological Society, on

Fatal Nausea and Vomiting of Pregnancy.

with the report of two cases. The conclusions at which the author arrives from his experience are: Nausea and vomiting of pregnancy are dangerous in proportion as they induce pernicious anæmia. Such a condition of danger is to be recognized by studying these cases in the light thrown upon them by the pathology of anæmia. While it is possible that sudden and radical improvement may occur in cases where a functional neurosis is the predominant factor, only when pernicious anæmia is once established delay is dangerous, no matter at what period of pregnancy the patient is seen. While it is true that raising and sustaining an impacted utures will relieve many milder examples of this affection, cases in which danger threatens should be set by prompt dilatation and emptying of the pregnant uterus, which is to be done by modern surgical methods.

Dr. Thomas Cunningham contributes an ticle on

Malignant Growths of the Uterus,

dwelling on the importance of early diagnosis in these cases. As there are very few symptoms in the early history of cancers of the sexual organs, he thinks it would be well if the profession made it a rule to emamine all female patients vaginally whenever they present themselves for treatment about the time of life when important changes are going on, and which statistics show are favorable to the development of malignant growths. Leucorrhœal discharges of whatever character and at all times should be carefully looked into and the cause removed, if possible. Shooting pains and dull aches in the sacral or hypogastric regions ought not to be overlooked, for sometimes these will be the only signs that are present.

In the "Department of Pædiatry," Dr. E. P. Bernardy reports

One Hundred and Sixty Cases of Measles in Private Practice.

Whooping cough occurred twenty-three times in the series. The author therefore thinks that there must be some relation other than accidental between the two diseases. He considers the use of bromoform in this complication unsafe and useless. Belladonna, pushed to its physiological effects, acted nicely in a number of these cases; when it failed, which it often did, pictate of ammonia was employed with perfect success in almost every case. In the series there were but three deaths, due to the complications present. He is satisfied that his success was due to his insisting on the minutiæ of nursing and treatment being carried out. His treatment of the measles proper was simple. When complications arose, he then used whatever medicine was necessary freely; stimulants were given sometimes in large doses without hesitation when the necessity demanded.

The remaining papers in this issue are: "Extirpation of the Uterus in Diseases of the Adnexa," by J. M. Baldy, M. D. This paper was published in *The American Journal of Obstetrics* for July and has been reviewed in connection with that journal:

"Hysterectomy in Bilateral Diseases of the Appendages," by Florian Krug, M. D. (This paper appeared in *The American Journal of the Medical Sciences* for June. A review will be found in THE MEDICAL AND SURGICAL REPORTER for June 23d, page 898.

"The Treatment of Face Presentation," by Edward Reynolds, M. D., and "Symphysiotomy versus the Induction of Premature Labor," by Charles P. Noble, M. D., both appeared in *The American Journal of Obstetrics* for July and have been noticed in that connection.

THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES

for August. Dr. Mathew D. Mann contributes a paper on

Inflammation of the Ureters in the Female.

The author is convinced that ureteritis is common, that it is often overlooked, and that it is mistaken for other conditions in no way connected with it except in location. By palpation the ureters can be recognized, especially when enlarged by disease, as two cords, running from a point a little in front of the uterus and a little to one side of the median line, directed at first towards the sides of the pelvis, and then curving somewhat sharply backward until they go beyond our reach near the spine of the ischium. In front of the uterus their ends are separated by an inch or a little more of space.

The causes of inflammation the author enumerates as follows:

1. Injuries during childbirth.
2. Previous disease of the bladder.
3. Gonorrhœa.
4. Suppuration of the pelvis of the kidney.
5. Pelvic disease, such as pelvic peritonitis, cellulitis, and tumors.
6. Abnormal conditions of the urine.
7. Tuberculosis.

The ureters may be injured by pressure of the child's head or the blade of the forceps, the pendulum movement of the forceps being particularly likely to produce trouble. Especially is it likely to occur if the head pushes down an undilated cervix and the bladder with it. The author has noticed an irritation lasting a long time, evidently started by the pressure of the child's head. Gonorrhœa may extend from the bladder to the ureters though the author acknowledges that gonorrhœal cystisis is rare in women. Yet he states that he has seen several cases in which this occurred and he has no doubt that many of the failures to obtain relief from pain after celiotomy for pus tubes are due to coincident but enrecognized gonorrhœal ureteritis.

The author has very little faith in the extension of inflammation from contiguous structure, except along the surfaces. He does not believe that ureteritis ever follows an inflammatory action in the tubes, ovaries, pelvic peritoneum or parametrium by direct extension. If the two coexist, he would look either for a common cause in a gonorrhœal infection, or the ureteritis may be due to the inflammatory exudation causing pressure and obstruction. Still less is he able to believe that an anteflexed and fundus can by pressure, even for a very long time, and "under conditions favoring the progress of the disease," induce a ureteritis, pyelitis, and pyelonephritis. He further protests against the doctrine that vesical irritability may be due to the pressure of an anteverted or anteflexed uterus. In such conditions he has never failed to find some other cause for the vesical irritability, usually in an abnormal condition of the urine.

The condition spoken of "renal insufficiency," the author believes is often a result of stimulation of the inhibitory influence of the nerve centers, due to peripheral irritation in the sexual organs. It is often found associated with ureteritis and, the author is fully persuaded, often stands in the relation of cause and effect.

That condition of the urine which is characteristic of the condition known as lithæmia is, in the author's opinion, the most common cause of the ureteritis.

In regard to the pathological condition, the author states that usually both ureters are affected; but often one side—usually the left—is much more seriously involved than the other.

As to the symptoms, the author states that the most common symptom is frequent micturition, which may even become continuous. In only a few cases out of those he has met has this symptom been absent. The next symptom of importance is pain over the ureters—one or both—the left side being more commonly affected than the right. This pain is described as burning or boring, and is nearly constant, but is almost always greatly aggravated as the menses approach, even be-

ing agonizing during the flow. One curious symptom which the author has noticed as frequently existing in cases associated with renal insufficiency is an absolute distaste for water.

The diagnosis is to be made, first by the symptoms; secondly, by the physical examination, and thirdly, by an examination of the urine. The palpation of the uterer in the pelvis is done as follows: The finger is carried along the anterior vaginal wall upwards and outwards near the brim of the pelvis to one side of the uterus. It is then passed forward, stroking the pelvic wall and carefully feeling for a cord-like body under it. Sometimes a bimanual examination will greatly aid in discovering the ureters. In every case that the author has seen, tenderness on pressure was present, and sometimes to an extreme degree. A feeling of a desire to urinate is often complained of on touching the ureters. By tracing the course of the ureters carefully with the finger tips, disease of the bladder and uretha may be excluded. Should bladder tenderness co exist it will be hard to distinguish the ureteritic disease unless the ureters are enlarged, or at least distinctly palpable.

The examination of the urine is an absolute necessity and no examination can be considered complete unless it embraces an estimation of the amount of urine passed in the twenty-four hours, as well as a careful chemical and microscopical examination. The urine will often be scanty; always acid in reaction; often hyperacid, unless cystitis coexists, and often of low specific gravity, 1010 to 1015. The sediment will consist of urates, uric acid, calcic oxalate, often pus, and a little epithelium. All attempts to locate the seat of the disease by the presence of peculiar types of epithelial cells will fail.

In regard to the prognosis, the author states that if the trouble has not lasted very long, and the ureters are not much enlarged or thickened, tho prognosis is good, though the time necessary for a cure will be considerable.

As to treatment, besides general out door exercise and measure to promote the general health, there should be a careful regulation of the diet and the urine kept as unirritating as possible. In many cases sugar and starches seem to be poorly digested and thus do harm and are to be avoided. Alcoholics, especially wine and beer, must be given up. In cases where there is renal insufficiency the author advocates the use of the hot air bath or a Turkish bath. Massage is also of great use in these cases and can be used immediately after the bath. The use of alkalies is of the utmost importance, and they should be used long and persistently, in sufficient quantity to keep the urine alkaline or at least neutral. Constipation is to be avoided. If anæmia exists, the use of iron and arsenic will be beneficial. The author has seen good results follow an exclusively milk diet. In regard to remedies that have a local action he speaks in praise of sandalwood.

The direct treatment by means of catheterization of the ureters, advocated by Kelly and the surgical treatment of the disease are also discussed in the paper.

Dr. James D. Heard describes in a paper entitled,

Certain Cases of Heterotopia of White Matter Occuring in the Human Medulla Oblongata,

comes to the conclusion that the central nervous system possesses, like other organs, a tendency towards occasional misplacement of its elements. The most frequent and fairly constant histological anomaly appears to be the presence of a column of white nerve fibres arising at the level of decussation of the pyramids, and thence proceeding upwards, occupying a position internal to the substantia gelatinosa. The fibres of this column may take origin from the lateral or from the posterior column. In certain instances these fibres have been traced above into the corpus restiforme, but this termination has seemed improbable in other cases in which the fibres have apparently extended to a much higher point.

Dr. W. Gilman Thompson contributes "Notes on the Observation of Malarial Organism in Connection with Enteric Fever," and gives as his opinion that while it is unwise to accept the term typho-malarial fever as indicating a third form of disease, which is neither typhoid fever nor malarial fever, it cannot be denied that the two latter diseases may coexist.

The other papers in this issue are: "The Isolated Type of Friedrich's Disease," by H. J. Mackay, M. B., C. M., Edinburgh. "A Study of One Hundred and Thirty-eight Cases of Pott's Paralysis," by J. H. Huddleston, A. M., M. D. "A Clinical and Experimental Study of Uræmia," by William E. Hughes, M. D., Ph. D., and William S. Carter, M. D. (Concluded in next issue.) "Round-Celled Sarcoma of the Anterior Mediastinum; Extensive Metastasis, including the Brain, both Choroid Coats, Oculo-Motor and Optic Nerves, and External Ocular Muscles," by Arthur V. Meigs, M. D., and G. E. DeSchweinitz, M. D.

Malakin.

F. Merkel (*Munch. med. Woch.*) observes that this drug has been recommended as an antipyretic, antirheumatic, and antineuralgic. It is a salicylic derivative and contains about 50 per cent. of salicylaldehyde; thus 4 g. corresponds to a little more than 2 g salicylic acid. The author has tried malakin in 18 cases, 15 of acute rheumatism, 2 of enteric fever, and 1 of neuralgic pains in typhlitis. Its action is very mild, and no unpleasant bye-effects are noted; at most the profuse perspirations generally following its administration might be looked upon as unpleasant. Perhaps the quality of the pulse suffered occasionally. The drug has a distinct antipyretic effect, but this is not permanent. As an antirheumatic it can produce a decided improvement in the articular manifestations. In 15 cases of acute rheumatism a favorable effect was noted in nine, and in two of these other remedies had been used without benefit. The author looks upon malakin as an addition to our resources where other remedies fail. Whether it can be given like the salicylates in larger and more frequent doses remains to be shown.

PERISCOPE.

IN CHARGE OF WM. E. PARKE, A.M., M. D.

GYNECOLOGY.

Small Cystic Degeneration of the Ovary.

Francis Foerster, in the *American Journal of Obstetrics*, 1894, presents the results of comparative microscopical studies of the ovaries as follows:

1. Small cysts are of common occurence, not only in human ovaries, but also in those of the sow, ewe, and the cow.
2. In accord with the researches of Nagel, I am convinced that the small cysts are originally Graafian follicles.
3. In a process not exactly pathological, the stratified epithelial lining of the Graafian follicle undergoes peculiar changes tending to its disappearance.
4. The epithelium first breaks up into an indifferent or medullary tissue, and from this arises myxomatous, vascularized connective tissue.
5. The type of the newly-formed myxomatous tissue varies in different animals. It may be medullary myxomatous lymph tissue, or fully developed myxomatous tissue with a well-marked basis substance.
6. The newly-formed myxomatous tissue is always scantily supplied with blood vessels, which probably grow into it from without.
7. The myxomatous lining of the cyst-wall is always well defined towards the outer fibrous coat, the original capsule of the Graafian follicle.
8. The ovule is present at the beginning of the formation of a small cyst; later it probably perishes, owing to the changed environments.

MEDICINE.

A New Method of Diagnosis and Prognosis of Chronic Nephritis.

Dr. Basset, of Toulouse, in a paper read at the International Medical Congress held in Rome, said that as long ago as 1860 he had read a paper before the Medico-Chirurgical Society of Toulouse, on "The Non-Elimination of Odorous Substances by the Kidney, as Bearing Upon the Diagnosis and Prognosis of Nephritis." Since that time he had found a new and more precise method of arriving at this end, namely the employment of iodides and of the salts of quinine, the elimination of which by the kidneys is so rapid in the normal condition, and the comparative dosage of which may be made so exactly. The following were the conclusions of the communication :

1. The elimination of odorous substances by the kidneys is retarded, diminished or abolished in chronic nephritis.
2. This examination of the odor of the urine is an easy and rapid method of ascertaining the functional condition of the kidneys and of determining their anatomical integrity or the reverse, and thus of arriving at a diagnosis and prognosis of Bright's disease.

The salts of certain substances which are ordinarily elimited in great part and rapidly by the kidneys, such as the iodides, the bromides, the salts of quinine and the turpentines, which form with nitric acid a precipitate soluble in ether and alcohol, are very useful as furnishing in a precise manner, by the retardation or diminution of their elimination in the urine, data upon which to base a diagnosis or prognosis of the various degrees of chronic nephritis.—*Maryland Medical Journal.*

Treatment of Renal Disease.

Dickinson (*The Lancet*), expresses the following views as to the treatment of nephritis:

Acute nephritis.—The disease has a tendency to recover spontaneously, qualified especially in scarlatinal nephritis by a tendency to fibrosis. Warmth in bed and a liquid diet are essential to recovery. The food should be milk, animal broths, and a moderate amount of farinaceous food. Water and aqueous drinks should be given freely. After a calomel purge it generally suffices to give a saline. Digitalis is to be given only if there is dropsy or if the urine be very scanty. Even though the urine contain blood no drug should be taken to check the flow, as it is rather beneficial than otherwise. The usual diuretics are useless and even harmful, cantharides being especially harmful.

Chronic albuminuria may continue almost indefinitely without much apparant injury to the patient. The heart will hypertrophy as a salutary adjustment, and the dropsy may be indefinitely postponed. In a quiescent case temperance in diet is much to be preferred to austerity. Farinaceous and vegetable food my be allowed without restriction, milk in abundance, watery drinks freely, and the less alcohol the better. A purely milk diet is not advantages. When urine is scant and of low specific gravity, large amounts of liquor should be taken. It is often necessary to save life. In movable cases it is well to have the patient in a warm climate with a low relative humidity. So far as medicines are concerned it is a good practice to give a ferruginous laxative combined with a small dose of strychnine. The normal termination of the granular kidney is by uremia. Sweating should be enforced where the uremia is indicated by headache, vomiting, etc. A Turkish bath every ten days may long ward off what would otherwise happen, or a hot air bath by a lamp under a sheet may be used. If the patient be weak, it is much better to give a partial hot-air bath than to envelop the whole body. The legs may be alone enveloped in the sheet

and this will be most invaluable in many instances.

Treatment of the Dropsy.—Nature's cure is hypertrophy of the heart. Measures which lessen the contents of the vessels and increase the force of the heart are indicated. Digitalis is almost invariably indicated. Most diuretics are useless; some are harmful, as cantharides. Vegetable salts of potash may be used. Hydragogue purgatives have their use. The abdomen may be tapped when there is excessive ascites, but the legs must never be tapped. Renal asthma admits of relief with alcohols, ethers and amyl nitrite.—*Univ. Med. Magazine.*

Nucleo-Albuminuria.

Pichler and Vogt (*Centralbl. f. inn. Med.*), observe that a more exact examination has shown that proteid substances in the urine do not only consist of serum, albumen, and globulin; nucleo-albumen is characterized by its solubility in acetic acid, its precipitation by magnesic sulphate, and by the separation on boiling with dilute mineral acids of no re ducing substance. It must be distinguished from globulin and mucin. Nucleo-albuminuria seems to appear when any damage is done to tissue cells, or more seldom when secretions holding nucleo-albumen, such as bile, get into the blood. In experiments on dogs, the authors show that the injection of casein produces nucleo-albuminuria. The simplest way of damaging protoplasm is to limit the supply of oxygen, and in these cases lactic acid, etc., appears in the urine. The authors demonstrate by their experiments on animals that temporary obstruction of the femoral artery will give rise to nucleo-albuminuria. In four experiments on dogs in which the renal artery was temporarily obstructed nucleo-albumen appeared. Serum-albumen was absent in one case, and only present for a short time in the others. The only changes found in the kidney were fat in the cells, and some alteration in the protoplasm belonging to the cells of the convoluted tubes. Experiments thus show that the renal tissue may be the source of nucleo-albuminuria, and this source must be excluded before others are thought of. The so-called cyclical albuminuria is often nucleo-albuminuria. In some cases of temporary compression of the chest or limiting the blood supply to a limb in young people albuminuria may be produced, but nucleo-albumen is more the exception here than the rule. These researches show further reasons for separating nucleo-albumen from ordinary albumen. The authors' investigations in the case of disease yielded similar results to those of Obermayer.

Treatment of Atonic Gastric Dilatation.

Wegele (*Munch. med. Woch.*) deals with the severer forms of this disease, and not with such as accompany any gastric affection lasting over any considerable time. For the practical distinction of mild from severe cases, the test breakfast is useful; in marked cases remains of food are found in the water used for washing out the stomach on the following morning, whereas in mild cases the stomach is able to deal with such moderate demands. Pronounced atonic dilatation is not, in the author's opinion, such a rare event as is sometimes represented. At first the dry diet was employed, and for slighter cases it sufficed; but a rigorous carrying out of this regimen was often of disadvantage. Washing out the stomach proved a great advance, as in this wash the stomach was freed of every acid and fermenting contents. Here, however, a considerable amount of nourishment is withdrawn, and the patient's nutrition and weight may suffer. Rectal alimentation must in addition be had recourse to; either water alone or the desirable food stuffs may be thus used. The amount of urine passed is a practical measure of the gastric insufficiency. By a strict dry diet and supplying the necessary water by the rectum, the patients condition may be greatly improved. Clysters containing grape sugar are apt to ferment and to produce diarrhœa, and the same is true of those containing peptone frequently repeated. The diet must be suited to the condition of the gastric chemistry. If hyperacidity is present large doses of alkalies are indicated. Washing out the stomach is, according to the author, best done in the morning. Raising the foot of the bed is said to be useful in helping to empty the pyloric antrum. If fermentation is present, harmless antiseptics should be added to the water, and salicylic acid, creosote, bismuth, salicylate given internally. If the adominal walls are lax, a belt should be used. The author says that the prognosis is considerably improved by the use of the dry diet, and supplying food by the rectum.

Dulcin.

Kobert (*Centralbl. f. inn. Med.*) says that pure saccharin is described by many as not being really sweet. Dulcin, discovered by Berlinerblau, has a pure sweet taste, and excels saccharin in sweetness some 200 to 250 times. In structure it is an aromatic urea derivative—paraphenetol carbamide—and is allied to phenacetin. It is soluble in 800 parts of water at 15° C., in 50 of hot water, and in 25 to 97 per cent. of alcohol. Experimentally dulcin has been shown to be harmless to rabbits, but in dogs, which are more susceptible to its action, the evidence is somewhat conflicting. From his own experiments on cats, the author concludes that doses corresponding to such as would be used in man are harmless; with abnormally large doses the cats became ill, and eventually died with cerebral symptoms. In diabetes it must be used in relatively small doses. Ewald has given it in doses up 1.5 g. in the day. The author concludes that dulcin in reasonable doses is, as far as we know at present, harmless, and is an advance upon the use of saccharin, owing to its sweeter taste. It does not bring about any decomposition of the blood.

Ether Spray in Coccygodynia.

Dr. E. McFarlan, New York, reports in *The American Therapist* an obstinate case of coccygodynia completely relieved by local ap-

plication of the ether spray. The first application was made over the entire sacrum and coccyx and continued for about five minutes, at first seemingly intensifying the pain, but this was followed by relief lasting through the day and night. The second treatment the next morning produced almost immediate relief. After the third application, the victory was complete. The daily use of the ether was continued for one week and now, after many months, there has been no return of the disease.

Throat Conditions Observed in Gouty Subjects.

S. Solis-Cohen (*Phil. Med. News*,)—Inflammation is not necessarily present in gouty sore throat. In the author's experience, the most prominent symptoms have been of a sensory nature, viz: pains and perversion of sensation over limited areas which, to the eye present no alteration whatever. The site most frequently complained of is the left pharyngeal angle just behind the free border of the soft palate; other areas are the general region of the epiglottis and base of the tongue. The pain is described as burning, stinging, pressing, etc. With most patients, cocaine applied locally, will for a time abate these paræsthesiæ. Where it does not, the deeper fibrous structures of the pharynx are probably involved.

Occasionally, during a gouty exacerbation, visible alterations of structure are manifested over the painful areas. The vessels dilate, the follicles enlarge and the mucous membrane may take on a dusky hue, or become of a "corn-beef" color.

Where the gouty manifestations appear in the larynx, the arytenoid eminences seem to be a favorite seat of morbid sensation. The crico-arytenoid joint may, as in rheumatism be the point on which the systemic state focuses. The natural activity of this articulation causes pain on respiration as well as in attempted phonation.

Local treatment is palliative only. Cohen prefers the glyceral of tannin applied by cotton wad, or the spray of sulpho-carbolate of zinc —5 gr. to rosewater 1 oz Applications of coca, fluid extract or infusion, may give relief where cocaine is badly borne or is for any reason contra-indicated. Aconitine oleate (2 per cent. in oleic acid), menthol in liquid petrolatum, bromoform, are all useful. In the more chronic cases, iodine with potassic iodide in glycerin, and carbolic acid, forms a valuable topical agent.

Thorough cleansing with a alkaline aromatic spray is a necessary prelude to all applications. For systemic treatment the usual measures are adopted against the uric acid diathesis. Strontium bromide has given the author much satisfaction.—*A. M. S. Bull.*

Special Exercise to Correct and Prevent Constipation.

Friction, rubbing or massage over all parts of the abdomen two or three times per day by the patient himself, or less frequently by a good magnetic operator, will help to promote vital action of the bowels. If not convenient for the patient to walk or ride for exercise, he can secure the advantage of both in large degree by the following exercise, taken in his room.

Standing with the feet well apart, to broaden your base, bend or flex the lower limbs at the knees and extend the same about twice a second, or one hundred times a minute, for several minutes at a time, three or four times a day and at the same time twist or turn the body above the hips first to the right and then to the left as far as you well can, resting the hands upon the hips or allowing them to hang by your side. At each turn of the body toward the right or left you will bend the knees about three or four times. You thus use chiefly the flexors and extensors of the thighs and the rotating muscles of the trunk. The motion of the body is meanwhile up and down, and the motion of the chest and head is alternately to the right and left. To facilitate the turning of the body, the heel of the limb opposite the one on which you rest, as the body sways from side to side, may be raised so as to allow the limb to turn upon the ball or toe of the foot To get the best effect of this exercise, the head must be kept well up, the shoulders back and the spine erect during exercise. The bowels may generally be allowed to rise and fall with the body, but at times it is well to exercise the diaphragm by endeavoring to draw beneath it the liver and viscera of the abdomen.—*Jour. American Health Society.*

Venesection in Renal Asthma; Instant Relief; Uric Acid in the Serum.

I was hastily summoned to this patient on November 20th, 1893, in the absence of his ordinary medical attendant, and found the symptoms so urgent that I was obliged to act alone and at once. The case was that of a man, aged 52, who had been under treatment for albuminuria and dropsy for rather less than a week. I found him in a state of orthopnea, and tossing about in bed in his distress. Expiration was prolonged and accompanied with loud dry rales; the pulse was somewhat slow—the actual rate was not noted—and, as it appeared to me, of markedly, high tension.

I immediately bled the patient *pleno rivo* to 15 ounces, with the result that he could at once lie down and that all the distressing symptoms had disappeared next morning. He was afterwards in the Western Infirmary for some time, and there is reason to believe that the attack has been an acute one, and not likely to merge into chronic Bright's disease.

Having previously discovered crystals of uric acid in the serum of two cases of convulsions which I had bled, and being much interested in the important researches of Dr. Haig on uric acid in the causation of disease, especially headache, high-tension pulse, convulsions, epilepsy, etc., I forwarded a spec-

men of the blood to him in the above case, which he was so kind as to examine. He reports as follows on November 24th, 1893:

"The specimen of blood you sent me on November 21st contained uric acid to the extent of 0.015 per cent. My experience with blood drawn during life is too small to draw any sweeping conclusions from; but the largest quantity I have found in blood of venesection was 0.03 per cent. in a case of cerebral hemorrhage, I have often found smaller amounts, 0.002 to 0.004. I should think, therefore, that 0.015 per cent. represents a distinct excess of uric acid, but that double this quantity may be found in some cases."—*Canadian Practitioner.*

Anthrax in Man.

Muller (*Deut. med. Woch.*, June 14th, and 21st, 1894,) refers to different views in connection with local treatment. It is impossible to destroy the disease by excising the site of inoculation. In guinea-pigs amputation of a limb two or three hours after the foot has been inoculated cannot save the animal. By the time the injection is ended absorption must have commenced, as is shown by the rapid proliferation of the bacilli in the tissues. The disease produced by anthrax would appear to be largely due to a toxic action. It may, however, be difficult to find bacteria in the blood; when absorbed they may be deposited in parts where the circulation is slow as in the liver, spleen, and marrow of bones. It has been shown with almost certainty that products may be isolated from anthrax cultures, which produce symptoms like those due to anthrax. Whether phagocytosis plays a part in human anthrax is undecided. The author's observations would lead to a negative conclusion. Different organs have difficult capabilities of dealing with anthrax. Thus, in rats the spleen seems to have chief action, but in rabbits the liver. In man enlargement of the spleen is noted early. It must be the object of treatment to get the cells at the site of inoculation to arrest the dissemination of the bacteria and to protect the cells in the whole body against the poisoning. If excision of the inoculated part cannot arrest the disease, it might be thought that the anthrax bacilli and their products might be let out by incision. The author concludes, however, that incision should not be practiced. Anthrax is one of the most virulent of the blood parasites, and by incision there is the danger of a fresh invasion of the blood in the vessels thus laid open. The products at the site of inoculation are harmful to the individual if absorbed, but they are also destructive to the anthrax bacilli *in situ*. The line of treatment recommended by the author is the following: The affected part and adjacent joint are fixed to prevent dissemination. The limb is also elevated to assist the venous return, so that more arterial blood may come to the part. Mercurial ointment is applied to prevent secondary infection. Means are adopted to improve the circulation, such as alcohol in large doses and nutritious diet. All the cases, including severe ones, which have been thus treated in von Bramann's clinic since 1890 have recovered.—*British Medical Journal.*

The Abuse of Milk in the Treatment of Albuminuria.

Lecorche and Talamon (*Bl. f. klin. Hydrotherapie*) condemn the indiscriminate use of milk alone as the diet of those who suffer from albuminuria. They fully recognize and admit the advantages to be derived from an exclusively milk diet, but they maintain that each must be judged on its individual merits, just as with every diet or medicament. They contest the view that milk of itself will provide sufficient nourishment for an adult; the rules that apply to the growing person cannot be transferred in full to the case of the fully grown. To preserve the balance of tissue change, an adult would require to take about four litres (about seven pints) of milk per diem, a quantity which, as experience shows, can rarely be taken, and then only at the risk of digestive disturbances which make the expected benefits quite illusory.

It is, therefore, going upon a wrong principle to say that every case of albuminuria ought to be sustained on a diet of milk only. Besides, the hope that by this diet albumen can be made to disappear from the urine is altogether vain, at least such is the experience of the writer's after a long and persevering research. They believe a strict "milk regime" is justifiable only when an excessive diuresis is indicated; that is, above all, in acute nephritis, and in the second place, in acute exacerbations of chronic inflammatory disease of the kidney.

It does not matter whether these exacerbations manifest themselves by hemorrhage, albuminuria or uremia. But this mode of treatment must not be carried too far; after a week or two the ordinary diet must be resumed, and the medical attendant must have recourse to other methods in his struggle with the primary disease.—*Glasgow Med. Journal.*

Imcubation Period of Infectious Fevers.

The following table in *The Year Book of Treatment* for 1894 is of interest as giving the views of the Clinical Society of London on the "Incubation Period of Infectious Fevers."

Disease.	Min. No. Days.	Most usual No. Days.	Max. No. Days.
Scarlet Fever . .	1	2	7
Diphtheria . . .	2	2	7
Influenza	1	3	5
Measles.	4	10	14
Variola	9	12	14
Enteric Fever . .	5	12	23
Varicella	13	14	19
Rubeola	8	18	21
Mumps	12	19	25

Diseases of the Heart Muscle in Typhoid Fever, Scarlet Fever, and Diphtheria.

Romberg (*Deutsche Archiv fur klinische Medicin*, Vol xlix, parts 4 and 5). In typhoid fever the highest grades of parenchymatous degeneration of the heart-muscle are present by the end of the second week, and then disappear but slowly in the later weeks. Interstitial myocorditis begins mostly at the end of the second week. In scarlet fever interstitial myocarditis begins mostly on the fourth day, and becomes excessive in the middle of the second week. In diphtheria this degeneration begins somewhat later, at the seventh or ninth day, and is at its highest development at the end of the second or beginning of the third week The characteristic fatty degeneration of diphtheria begins often very late. Symptoms during the fever: irregularity and smallness of the pulse and dilatation. The best sign of dilatation is the gallop rhythm. A very slow pulse is a bad prognostic sign in diphtheria. Dilatation is an important physical sign. The amount of urine is usually diminished; there is slight albuminuria with or without hyaline casts.

Myxedema Treated by Thyroid Extract.

Shattuck (*Boston Medical and Surgical Journal*,) reports four cases of the disease treated with the dried extract of the thyroid gland. Three of the cases were, undoubtedly myxedema, and are examples of cures. The first case, however, presented some difficulties in diagnosis, and was not improved in the least by the treatment. In remarking upon the cases he says that in the first place we must recognize that there are differences in degree. Total inactivity of the gland is one thing, partial inactivity another. It is highly probable that the latter does not necessarily lead to the former. At all events, long periods of years may elapse before the mild passes into the fully-developed disease. Now that our attention is awakened he is convinced we shall find them pretty common. The dosage is important. In one case seven and a half grains of the extract were given at a dose. This caused terrible angenoid attacks, which required morphia to control them. Pain in the limbs and backs have been noticed as caused by the treatment. It is well to begin with very small doses,—one grain of the extract twice daily,—and gradually increase it. It is probable that the treatment will have to be continued through the life of the patient, and that larger doses will be required in cold than in hot weather. —*University Medical Magizine.*

ARMY AND NAVY.

CHANGES IN THE U. S. ARMY FROM AUGUST 25, 1894, to SEPTEMBER 1, 1894.

Major John D. Hall, Surgeon, upon the arrival of Major J. C. Merrill, Surgeon at Fort Sherman, Idaho, will be relieved, and report for duty at Madison Barracks, N. Y., relieving Major Daniel G. Caldwell, Surgeon.

Major Caldwell on being thus relieved, will report for duty at St. Francis Barracks, Florida, relie ing Captain Jefferson R. Keen, Assistant Surgeon.

Captain Kean on being thus relieved, is ordered to Key West Barracks, Florida, for duty.

Major Louis M. Maus, Surgeon United States Army, Fort Sam Houston, Texas, granted one month leave of absence.

Leave of absence for one month, to take effect when relieved from duty at St. Francis Barracks, Florida, is granted Captain Jefferson R. Kean, Assistant Surgeon.

Captain Louis A. La Garde, Assistant Surgeon, relieved from duty as Attending Surgeon, and Examiner of Recruits, Headquarters Department of the Colorado, and ordered to Fort Logan, Colorado.

By direction of the Secretary of War the following changes in the station and duties of officers of the Medical Department are ordered:

Major W. H. Gardner, Surgeon, relieved from duty at St. Paul, Minnesota, and ordered to Fort Custer, Montana, for duty.

Major Henry McElderoy, Surgeon, relieved from duty at Omaha, Nebraska, and ordered to Fort Robinson, Nebraska, for duty.

Major George W. Adair, Surgeon, relieved from duty at Fort Robinson, Nebraska, and ordered to Washington Barracks, S C., for duty.

Major Joseph H. Corsin, Surgeon, relieved from duty at Washington Barracks, S. C., and ordered to Fort S. A. Russell, Wyoming, for duty.

First Lieutenant Frederick P. Reynolds, Assistant Surgeon United States Army, United States Military Academy, West Point, N. Y., granted 30 days leave absence.

CHANGES IN THE U. S. MARINE HOSPITAL SERVICE, FOR THE FIVE WEEKS ENDING AUGUST 25th, 1894.

P. H. Bailhaehe, Surgeon, granted leave of absence for five days, August 3d, 1894.

J. B. Hamilton, Surgeon, granted leave of absence for five days, August 16th, 1894.

H. W. Sawtelle, Surgeon, granted leave of absence for five days, August 12th, 1894.

J. M. Gassaway, Surgeon, granted leave of absence for two days, August 11th, 1894.

W. Stonerly, Surgeon, granted leave of absence for seven days, July 28th, 1894.

Fairfax Irwin, Surgeon, to proceed to Brussels, Belgium, for special duty on July 24th, 1894, to Rotterdam, Netherlands, July 27th, 1894, to proceed to Hull, Liverpool, and other English ports on special duty August 9th, 1894.

F. W. Mead, Surgeon, granted leave of absence for thirty days, August 4th, 1894.

C. E. Banks, Past Assistant Surgeon, to proceed to Halifax, N. S., for special duty August 16th, 1894.

A. H. Glennan, Passed Assistant Surgeon. Granted leave of absence for six days August 14th, 1894.

S. D. Brooks, Passed Assistant Surgeon. To proceed to Duluth, Minn., and Superior, Wis., as Inspector, July 24th, 1894.

J. H. White, Passed Assistant Surgeon, relieved from duty at Savannah, Georgia, and

ordered to report to the Medical Official in command of the Service at New York, N. Y., for duty, August 6th, 1894.

P. M. Carrington, Passed Assistant Surgeon. To proceed to Evansville, Indiana, for duty, August 6th, 1894.

J. J. Kinyoun, Passed Assistant Surgeon. To proceed to Buda Pesth, Austria, to represent Department at International Congress of Hygieu and Demography, August 14th, 1894.

G. F. Vaughan, Passed Assistant Surgeon. Granted leave of absence for six months, August 23rd, 1894.

C. P. Wertenbaker. To report at Bureau for instructions August 4th, 1894. To proceed to Cape Charles Quarantine for temporary duty, August 7th, 1894. To proceed to Delaware Breakwater Quarantine for duty August 20th, 1894.

Assistant Surgeon, C. H. Gordner, granted leave of absence for fifteen days August 18, 1894

Assistant Surgeon, Seaton Norman, to proceed to Baltimore, M. D., for duty August 6, 1894.

Assistant Surgeon, E. K. Sprague, to inspect unserviceable property at St. Louis, Mo., July 26, 1894.

PROMOTIONS.

Assistant Surgeon, E. R. Houghton, commissioned as Passed Assistant Surgeon, July 20, 1894.

NEWS AND MISCELLANY.

Dr. Charles P. Noble has removed to 1637 North Broad street, Philadelphia.

Dr. Charles W. Burr has removed to 1327 Spruce street, Philadelphia.

American Public Health Association.

The American Public Health Association will convene at the city of Montreal, Canada, Tuesday, September 25, 1894 at 9 o'clock a. m., and continue four days.

The regular sessions will be in Association Hall, Y. M. C. A. Building, Dominion Square, opposite the Hotel Windsor. The following topics have been selected for consideration at this meeting:

1. The polution of Water-Supplies.
2. The Disposal of Garbage and Refuse.
3. Animal Diseases and Animal Food.
4. The Nomenclature of Diseases and Forms of Statistics.
5. Protective Inoculations in Infectious Diseases.
6. National Health Legislation.
7. The Cause and Prevention of Diphtheria.
8. Causes and Prevention of Infant Mortality
9. The Restriction and Prevention of Tuberculosis.
10. Car Sanitation.
11. The Prevention of the Spread of Yellow Fever.

Upon all of the above subjects special committees have been appointed; therefore all papers upon these topics should be presented to the appropriate committee in season to be incorporated as a part of the report of the committee, if deemed advisable.

The Executive Committee announces the following additional subjects upon which papers are invited:

12. On the Education of the Young in the Principles of Hygiene.
13. Private Destruction of Household Garbage and Refuse.
14. Disinfection of Dwellings after Infectious Diseases.
15. Inspection of School Children with Reference to the Eyesight.

English, French and Spanish will be the official languages at this meeting. Papers may be read and discussions take place in either of these languages. All discussions will be stenographically reported for the use of the Association.

The American Public Health Association was organized in 1872, by a few public-spirited men who foresaw the need of bringing together in one body the ablest sanitarians in the country, for the purpose of inaugurating measures for the restriction and prevention of contagious and infectious diseases, and for the diffusion of sanitary knowledge among the people. Its membership has been augmented from year to year until now it constitutes the largest and strongest sanitary body in the world, and embraces in territorial extent the United States, the dominion of Canada and the republic of Mexico. Under the impetus given by its work, state and local boards of health and sanitary associations have been organized, sanitary publications increased, and hygienic knowledge widely and extensively diffused. The association has already published nineteen large and valuable volumes, increasing at the rate of one a year, and containing the papers, reports and discussions presented at the annual meetings. These volumes constitute in themselves a library upon sanitation; they are elegantly printed and bound, and are alone worth more to any person interested in hygiene than the cost of membership. Each member is entitled to the annual volume, delivered free of expense. In addition thereto, the association has published a standard work upon "Disinfection and Disinfectants," besides the Lomb Prize Essays, now so widely known to the American public.

Among its members may be found physicians, lawyers, ministers, civil and sanitary engineers, health officers, teachers, plumbers, merchants, etc.—in fact, every profession and many of the industries are represented in its list of members. The only qualifications required for membership are a good moral character, an interest in hygiene, and the endorsement of two members of the association. Cost of membership, five dollars a year. For blank applications for membership, or particulars relating to the association, address the secretary.

THE
MEDICAL AND SURGICAL
REPORTER.

No. 1959. SEPTEMBER 15, 1894. Vol. LXXI—No. 11

ORIGINAL ARTICLES.

IS VACCINATION WITH BOVINE VIRUS PERFORMED IN ACCORDANCE WITH THE SCIENTIFIC TEACHINGS OF THE DAY?

F. W. JAY, M. D., Chicago, Ill.

To carry out rationally a proper technique in the preparation and use of bovine virus, the nature of the vi us must be appreciated as well as the manner in which it confers immunity to individuals inoculated with it. At present, although the active principle of cow-pox virus has not been demonstrated, we can assume enough of its nature to allow of formulating positive rules regarding its management.

After an investigation of thirty years, Edward Jenner, in 1798, gave to the world the wonderful fact that immunity could be secured against small-pox by vaccination.

At that time bacteriology as a science was undreamed of, and knowledge concerning the most common etiological factor in disease production, bacteria, was yet to come; consequently Jenner could not assume facts in regard to the causative agent of small-pox or the active principle of his virus. Could he have done so, it would have allowed him to advance theories in regard to the manner in which immunity was conferred by vaccination and, as a result of these theories, to claim for the methods of preparation, care and use of his virus such a technique as bacteriology has shown us is essential in working with a material such as we assume this virus to be.

Bacteriology has not revealed the active principles of his virus to us, but it has made it possible for us to assume its nature with enough certainty to adopt definite rules for its preparation and application.

Although Jenner was not allowed the benefits of bacteriology, he had learned by observation of the action of his remedy for thirty years, that it was necessary to exercise care in its preparation and application in order to insure safe and reliable results. We find in his original paper (The Origin of the Vaccination Virus, by Edward Jenner, M. D.) such advice as this: "But when taken in a far advanced stage of the disease, or when (although taken early) previously to its insertion it be exposed to such agents as according to the established laws of nature, cause its decomposition, it can no longer be relied on as effectual. This observation will fully explain the source of those errors which have been committed by many inoculators of the cow-pox. Conceiving the whole process to be so extremely simple as not to admit of a mistake, they have been heedless about the state of the vaccine virus, and finding it limpid, as part of it

will be, even in an advanced stage of the pustule when the greater portion has been converted into a scab, they have felt an improper confidence, and sometimes mistaken a spurious pustule, which the vaccine fluid in this state is capable of exciting, for that which possesses the perfect character."

There are many physicians today who might improve their methods of carrying out vaccination by considering the paper from which I quote, although it was written a century ago. It was written in accordance with the best knowledge that Jenner had, and it is allowable for us to apply to his views, theories which the advance of science renders possible.

If, today, Edward Jenner was to bring to the world his discovery, he would assume that small-pox was an infective disease, the result of the invasion of the organism by a specific microbe; and that in the virus used to procure immunity by vaccination, he possessed a material, the active principle of which was either an attenuated form of this micro-organism or a product of its action in the cow.

"Vaccination appears to consist essentially in the artificial growth of a vegetable ferment in an animal, under circumstances unfavorable to its rapid multiplication."—Buist.

"Immunity is most frequently seen to follow the introduction into the body of the products of growth of bacteria that in some way or other have been modified. This modification may be artificially produced from the products of virulent organisms and then introduced into the tissues of the animal; or the organisms themselves may be so treated that they are no longer virulent, so that when introduced into the body of an animal they eliminate poisons of a much less vigorous nature than is the case when they possess their full virulence."—A. C. Abbott.

Pasteur began his researches on artificial immunity with the view that cow-pox virus was an attenuated form of small-pox virus, and that small-pox was a disease of microbic origin. As a result of experiments conducted under this belief, he was able to obtain vaccination virus capable of procuring immunity against several infectious diseases, notably hydrophobia. Others working with pure cultures of known bacteria have been able to establish methods of procuring immunity against many diseases, and the work has but begun. We are in sight of curative and preventive measures against tetanus, pneumonia, diphtheria, anthrax and tuberculosis, and even malignant growths are reported to have vanished under the influence of the streptococcus of erysipelas and its ptomaines. Pasteur conducts the preparation of his emulsions and the technique of their employment under a conviction that he is dealing with a material of microbic nature, and that in order to secure an action of his remedy, consistent with its nature, a method of procedure is necessary that will allow of little carelessness either in its preparation or its application.

Is the present method of vaccination in accordance with what is scientific and correct? Spend one hour in a Pasteur institute where inoculations are being made and observe the careful technique which the physicians in charge consider necessary to adopt, and then stand for an hour in the vaccinating room of the health department of this or any other city and observe the manner in which the vaccination is done. Why should one not be performed as carefully as the other? They are dealing with material of somewhat similar nature. Vaccination is not being performed at the present time in accordance with scientific teachings. We claim the same careful technique for the preparation and application of bovine virus as is granted the above agents.

As to the improvement of present methods:

1. We can assume that small-pox is an infective disease due to the invasion of the organism by a specific microbe, and that the active principle of Jenner's virus, which gives it its power to procure immunity for the individual inoculated with it, is due to the presence of an attenuated culture of this bacteria, or the product of its action upon organized tissues, animal or human, as the case may be.

This is theoretical—Specific microbes have been claimed for this disease but have not been demonstrated to be its causative agent. And for the virus that produces immunity; "it must be confessed that nothing was known as to the composition of the material by which typical vaccine vesicles are produced, until the researches of Weigert, Klebs, Cohn and Burdon Sanderson rendered it probable, if not certain,

that a "germ" was the active principle in vaccine lymph." (Buist.)

"The etiology of small-pox still remains undetermined. The common pus cocci, and various other micro-organisms are found in the characteristic pustular eruption, and various micro-organisms have been isolated from vaccine vesicles, but no one of these has been shown to possess the specific pathogenic power of unfiltered lymph from the same source.

"The experiments of Carstens and Coert show that the specific virulence of vaccine lymph is destroyed by ten minutes exposure to a temperature of 54° C.

"And the writer's experiments show that various disinfecting agents tested—chlorine, sulphur dioxide, nitrous acid—destroy the infective virulence of lymph dried upon ivory points in about the same proportion as is required for the destruction of some of the best known pathogenic bacteria.

"But this does not prove that virulence depends upon the presence of living micro-organisms, however probable this appears, for certain toxalbumins are likewise destroyed by a correspondingly low temperature, and by the action of various chemical disinfectants." (Sternberg.)

"The nature of the contagion of small-pox is still unknown. Weigert and others have described micro-organisms in the pock, but they are the ordinary pus-cocci, and the part which tney play in the affection is by no means certain. Still less definite are the observations on the occurrence of sporozoa in the pocks. It not a little remarkable that in a disease which is rightly regarded as the type of all infectious maladies, the specific virus still remains unknown.

"The precise nature of the vaccine virus is as yet unknown. Several forms of micro-organisms have been isolated, and Buist has cultivated micrococci which, he states, produces in the child a typical vaccine vesicle. Several attempts have since been made to isolate the virus, but without definite success. Ernst and Martin, of Boston, have isolated from the Bovine lymph, a germ which grows on culture media, and produces, when inoculated in the calf, or in children, characteristic vesicles." (Osler.)

The inability of bacteriologists to cultivate the essential microbe of vaccine lymph, Buist states, is due to faulty methods, and not to the mistakes of investigators. He says, "while, therefore, a bacteria of constant form, to be found in clear vaccine and variolous lymph, is probably the cause of variola and vaccine, it appears to be practically impossible to reproduce the same bacterial form by artificial cultivation of lymph in solid media outside the animal body."

The experiments of Buist have led him to conclude regarding the active principle of vaccine virus, that, "the bacteric form of the true vaccine contagion is to be found in the minute isolated spores of micrococci, which are suspended in standard vaccine lymph, and this form must be preserved in artificial vaccine materials; opaque vaccine lymph contains more mature bacteria forms developed from the spores in clear lymph and is to be regarded as a natural cultivation of the true vaccine contagion. The torulæ described in opaque lymph do not exist in clear lymph and their significance is doubtful, and most probably they represent a resting or reproductive stage of existence of the vaccine contagion. The vaccine contagion can be isolated and cultivated apart from the animal body, in both solid and fluid media.

"The pathogenic properties of the vaccine and variolous material depend on the embryonic and mature forms of bacteria which they contain."

2. Inoculation with pure bovine virus produces in a person not immune to small-pox, a characteristic reaction which demonstrates that immunity has been conferred upon the individual inoculated for an indefinite length of time.

The characteristic reaction is usually looked for in the local condition produced, but general symptoms may result from such vaccination.

"When clean vaccine lymph is properly employed, the resulting vesicle is plump, round or oval, and pearl colored, with an elevated margin and a depression or umbilification in its center; and it contains on the eighth day, or even earlier, a material which is identical in appearance and potency with that by which it was originally produced. On the eighth day the vesicle becomes surrounded by a rose-colored zone of inflammation, or areola, which continues to increase for several days, and the clear contents of the vesicle are then found to be opalescent or opaque. The establishment of this areola is re-

garded as a proof of the specific effect of vaccination on the constitution. From the eighth to the tenth day, the opacity of the lymph continues to increase, after which coagulation of the contents of the vesicle takes place with the gradual formation of a dry, brown scab by the fourteenth day. This scab becomes harder, dryer and darker during the third week, when it falls off leaving a depressed circular, or oval cicatrix, which is the natural termination of the process by which the majority of the human race are protected for a life time from small-pox. If such a termination to vaccination should be guaranteed with certainty, its beauty and symplicity could not be questioned."—Buist.

3. The virus (assumed to be due to specific bacteria, or the product of specific bacteria) may become contaminated by other micro-organisms, which will consequently be inoculated with it, and cause a mixed infection which may modify, inhibit or overcome the influence of the virus.

The channels through which the virus may be contaminated are so various that I can only hope to notice a few main sources. I shall not criticise individual manufacturers of virus. The majority of men engaged in the preparation of bovine virus, I assume to be conscientious. I shall simply speak of sources of infection, some of which I believe from reports of vaccine stations are not sufficiently appreciated. Manufacturers can hardly be censured when we consider the manner in which educated physicians carry out inoculations with the virus of their production.

The virus used to procure immunity against small-pox is either a pure culture of the essential cause of small-pox mitigated by having been passed through the calf, or it is a material containing a product of the action of the essential bacteria of small-pox in the tissues of the calf. That the former is true, we are convinced from the fact that filtered lymph has been proven void of the power to procure immunity. Accepting this theory, a pure virus is a pure culture of an unknown microbe, and is only pure when the essential microbe is alone present in it.

That the culture is often not pure in commercial virus, I am satisfied, although in the summary of results Buist claims that no other bacteria but the specific one of the virus will grow in the lymph. "My observations appear to show that when it is taken from a typical Jennerian vesicle, it is a material, in the contagion of which no second principle can possibly reside."

Buist obtained in his cultures a micro-organism of so many transitional forms, that the question of his having obtained a pure culture can be doubted, and hence he is not entitled to assume that but one microbe can be present and active in the material used for vaccination. That, theoretically, in a mixed culture the specific bacteria of the vaccine virus might be able to cope with and conquer the contaminating bacteria, is possible, but, practically, I am sure the opposite is often true and the contaminating bacteria prove the stronger. I feel certain that the virus dried on a point is absolutely unable to exert any combative influence on contaminating microbes which may be deposited upon it, as organic matter in a dry state is inactive. I believe that every one who has any part in the preparation of these points should have had some practical work in bacteriology, and should appreciate the care required to secure a pure culture of any bacteria, which, theoretically, must be accomplished to secure pure virus.

All the criticisms I have to make regarding the preparation or use of bovine virus points, concern methods which will allow of the virus becoming contaminated by micro-organisms other than the essential microbe assumed to be present in it and to be the essential factor in procuring immunity with it. Taking the steps in the preparation of bovine virus points in their order, we start with the points which are to be coated with the virus. The points to be inoculated from the vesicles must be aseptic or we have started wrong, and, of course, will fail in securing a pure virus. Such points are usually of bone—so called ivory points. To secure an aseptic condition of such material, it must be subjected to some anti-microbic influence. We assume it to be infected, as all material must be considered from a bacteriologist's view. The ideal method of sterilization, heat, cannot well be used with such a material, as the influence of heat, dry or moist, for a sufficient length of time, is detrimental to bone. Solutions of the recognized antiseptic agents, carbolic acid, or mercury

bichloride, or absolute alcohol, may be used. The first two have disadvantages in that they may remain in the material in sufficient quantities to inhibit or overcome the efficiency of the virus unless thoroughly removed from the points before inoculation. This, however, can be accomplished by careful rinsing with sterilized water. Absolute alcohol has the advantage of being a good antiseptic, and yet easily removed from the points by evaporation or rinsing with sterilized water. Absolute alcohol would, therefore, be a reliable method of preparing the material ordinarily used for points. That alcohol is a reliable antiseptic has been demonstrated by experimental research and clinical experience. Metal points would have the advantage of allowing disinfection by the only reliable sterilizing agent—heat, preferable in the form of steam under pressure.

Assuming the points to have been absolutely sterilized, there are great dangers of contamination from materials with which they may come in contact subsequent to their disinfection and during the processes they pass through before being sealed for shipment. The hands of the workmen would probably be the main source of such contamination. This source is worthy of consideration. Every day we notice great and learned surgeons—teachers of antiseptic surgery—who, although the most conscientious of men, will, during operations under so-called antiseptic precautions, overcome all the painstaking measures adopted to prevent infection by handling infected materials, never realizing the error, although perhaps at the same instant, addressing their audience upon the necessity of carefully carrying out all details in antiseptic methods in order to prevent infection. Knowing this, can we set aside the danger arising from the workmen in their care of the points, prior, during and subsequent to inoculation, even though the points are absolutely sterilized at the commencement. In many institutions a large number of points are placed in frames before being inoculated, and dried and all prolonged manipulation with the hands dispensed with. But simple contact is enough, and great care must be exercised even with the use of such frames. The workmen should wear a sterilized gown over their clothes, with arms bare, and hands and arms thoroughly prepared by antiseptic measures.

The virus used to coat the points may or may not be pure at the time it is applied to them. The part of the animal inoculated for the purpose of the vesicle production must be absolutely aseptic. All the care is necessary in this preparation that would be adopted in preparing an abdomen for a laparotomy. Shaving, green soap and sterilized water, and scrubbing with a brush, followed by a reliable antiseptic solution. The latter can be removed with sterilized water before inoculation. If such a surface is inoculated with a pure virus, with careful protection of the inoculation lesion from subsequent infection, which must be of great difficulty, we have some assurance that the vesicle produced may contain a pure culture of the specific germ.

The rooms in which the work is carried on, and the stalls in which the animals are placed should allow of frequent irrigations with antiseptic solutions. This is accomplished in some of the stations. But the greater danger, as in all infection, is from direct contact. The animals used for the purpose of virus production are selected with great care by the great majority of manufacturers. They realize the danger of carrying the contagion of tuberculosis and other diseases by the virus. Nevertheless, it is my opinion that this matter should be under close inspection by the government and not too much trust placed in private corporations.

When the vesicles are fully developed and the points are to be coated with the contained virus, nothing but sterilized substances should come in contact with the points or the virus, extraordinary care being taken by the workmen in the antiseptic preparation of their hands. The subsequent packing of the coated points in sterilized tubes of glass closed by sterilized corks, will enable the manufacturer to feel that he has carried out a method of preparation in accordance with the teaching of bacteriology.

If the point leaves the manufacturer in a pure condition, the subsequent condition of the virus and the result of the inoculation lie in the hands of the retailers and the one who uses them. We will simply mention the manner in which these points are retailed by druggists everywhere. Step in a drug store and buy one point, and one will need no words to be convinced that nu-

merous portals for the invasion of contaminating bacteria are opened during the procedure. Drug clerks and the laity who purchase these vaccine points and use them upon themselves and each other, may not be responsible for their ignorant mistakes, but educated physicians should realize that in making use of this most important prophylactic agent they are using material of some delicacy, and should adopt methods for its employment in keeping with the teachings of the day. They know, or should know, how to prevent contamination of vaccine points, and how to carry out the technique of vaccination in a manner that will allow of an inoculation with a pure virus, by the preparation of the site of operation, the use of sterilized water to moisten the virus and a protection of the scarifications from infection throughout the progress of the local lesions. The disinfection of the part should be by the thorough use of soap and water with brush, sponging with absolnte alcohol and then with sterilized water.

No antiseptic should come in contact with the virus, as the active principle is undoubtedly of a nature to be inhibited or made inactive by such substances. The part should be protected, subsequent to inoculation, by some aseptic material which covers but does not touch the scarifications. A sterilized bunion plaster to keep the protecting aseptic gauze from touching the scarifications, the whole dressing kept in place by a strip of adhesive plaster is simple and valuable.

4. The use of impure virus may lead to faulty assurance that immunity has been conferred, from the fact that the contaminating micro-organisms may, by exciting their specific pathogenic properties on the parts inoculated, produce a local lesion which may be mistaken for a typical vaccine reaction, when in reality the vaccine virus itself has been entirely void of any influence whatever.

This is frequently the case, and may mean much or little to the individual or the community according to circumstances. That Jenner knew such mistakes were possible is evident from his own words: "For I now discovered that the virus of the cow-pox was liable to undergo progressive changes from the same cause precisely as that of the small-pox; and that when it is applied to the human skin in its degenerated state, it would produce the ulceration effects in as great a degree as when it was not decomposed, and far greater, but having lost its specific properties, it was incapable of producing that change upon the human frame which is requisite to render it unsusceptible of the *variolous contagion.* So that when it became evident a person might milk a cow one day and, having caught the disease, be forever secure, while another person, milking the same cow the next day, might feel the influence of the virus in such a way as to produce a sore or sores, and in consequence of this, might experience an indisposition to a considerable extent, yet, as has been observed, the specific quality being lost, the constitution would receive no peculiar expression."

5. There is practically no danger in vaccination with a pure virus, but contaminating micro-organisms may be the immediate cause of danger to the part, or the life of the patient.

It is not necessary to insert any cases reported of the evil results following vaccination. They are more or less frequent and few are reported In comparison with the number of vaccinations produced, the evil results of a grave nature are very few. But erysipelas, prolonged ulceration, lymphangitis and suppurative adenitis are not uncommon, and a number of cases of tetanus have been reported. The danger of carrying syphilis has passed with the adoption of bovine virus, but tuberculosis is possible with this material. The fact that cases of serious infection are few does not lessen the responsibility of the physician if, by his negligence, a case occurs. It is his duty to make the few impossible. Considering the total number of hours lost from business, the discomfort and pain suffered by patients, the number of cases sent into the dangers of contagion with the assurance that they are protected by a vaccination which has been valueless as a protective measure, and the cases of death caused by vaccination with a contaminated virus, all of which could have been avoided if everyone connected with the preparation of the virus and its use, had made practical applications of the teachings of bacteriology, the advantage of which physicians of the past could not avail themselves but which at the present time we are masters of, I think the subject is one of real practical importance and worthy of serious reflection.

COMMUNICATIONS.

ICTERUS FROM EMOTIONS.*

PROFESSOR PONTAIN, PARIS, FRANCE.

We have at this moment in the hospital, two patients affected with icterus. The one is a rheumatic male patient with a catarrhal icterus; therefore we thought that anti-rheumatic treatment might be of service in his case, and after being for several days under the salicylate of soda, he has become convalescent. The other is a young woman who is not rheumatic, and who attributes her jaundice to a violent fit of anger. Her case may be classed among those cases of icterus which follow emotions.

In this variety one will meet with cases where the jaundice followed immediately after the emotion upon which it depends; in others, as in our patient, the affection is only noticed a few hours or one or two days after. Is the mechanism the same in both cases? Often emotional icterus is accompanied by causes capable in themselves of producing the disease, so that for a long time it was thought to be a mere coincidence or a ridiculous tale.

Still there are cases where the influence of the causative emotion is not to be doubted. I have reported to you several cases of instantaneous icterus. You recall Bouillaud's case: A man was about to shave himself. Suddenly some one comes and informs him of a loss which he has suffered; on taking up his razor he perceives in the mirror that he has become jaundiced. I have already mentioned the case of a young girl who went into a cellar and was unexpectedly bitten by a rat; very much frightened she ran out and was met by a person who noticed that she was icteric. Another case was that of a man who was seized by the Federals and was about to be shot; his wife, who was present, remarked that he immediately became jaundiced when the troops arrived from Versailles and saved him. It is told of a duellist, who, upon the duelling ground, in a twinkling of an eye became so yellow that the weapon fell from the hand of his adversary. Again, a man received a box on the ear; he precipitated himself furiously upon his opponent; he was at once arrested, when it was noticed that he was completely yellow. Still another case was that of a young priest who was present while a mad dog was to be shot; at the moment that he was struck by the bullet, the animal gave a bound into the air, broke his chain and expired at the feet of the priest. The latter, terribly frightened, fell to the earth and arose completely icteric. These are all authentic cases.

Often the icterus does not follow at once. In 1882, I observed at the Necker Hospital, a young girl, who had had a violent fit of anger; several hours after her eyes began to grow yellow and she became progressively icteric. In one case, a woman of thirty-one years had an attack of icterus eight hours after an accident. A physician of Montpelier has recorded the case of the interne of a hospital who was frightened by a comrade who played the part of a ghost. The interne was terrifically frightened by the apparition; the next morning he was jaundiced. The case of a young girl near Bordeaux has been observed, who, impressed with the reproaches of her father, a few hours later became icteric. Dr. Noblet has reported the case of a woman, who, while assisting to unload a wagon loaded with potatoes, all at once saw the man standing in front of her buried under an avalanche of potatoes; she experienced a vivid emotion; the next morning jaundice appeared. Finally, Hardy has called attention to the case of a young hackdriver who allowed his horse to run away; the following morning he was icteric.

An emotion is frequently found to be the cause of icterus, but the importance which it merits has not been attached to it. The nature of the emotion is variable; most generally it is terror. Sometimes, as in our patient, it is a fit of anger. Let us see by what mechanism the icterus is produced.

Instantaneous icterous is easily explained

* A clinical lecture delivered at the Hospital de la Charite, Paris, France. Translated from *L' Union Medicale*, No. 70, 1894, by F. H. Pritchard, M. D.

by the modifications of pressure between the capillaries and the small bile ducts. Normally the pressure in the bile ducts is greater than in the blood-vessels; in animals even without icterus this may be observed. But the biliary pressure is variable, for experiments have not yet given us exact knowledge on this subject. At all events, if the pressure in the ducts be increased the bile rapidly passes into the blood.

You will observe that if one tap the abdomen of a frog with the handle of a scalpel, the blood-vessels will become enormously distended; all the blood of the periphery seems to rush to the abdominal cavity. The same result may be produced by excitement of the cortical nerve centres, as Frank has demonstrated. Thus there is a lowering of the blood pressure in the capillaries of the liver, while at the same time there is an increase in that of the bile ducts and their capillary ramifications. Not every violent emotion is followed by icterus, but as I have stated, the pressure in these ducts is quite variable, now high, now low, and now negative. It is easily seen that if the variations in the blood pressure are to occur when that of the bile is high, icterus immediately follows. Yet these modifications of pressure are by no means all, for, as Laborde has shown, the biliary passages are contractile; any excitation will produce a slow retraction of their walls, with consequent elevation of pressure. Lepine, after introduction of a tube and a manometer into a bile duct, has observed the pressure to rise in a few minutes under the influence of excitement. If every emotion does not give rise to these effects it is because of a reflex influence. Now, reflexes are variable. They may act upon one part or another, they may be diffused, but they especially affect sensitive organs. Instantaneous jaundice has nothing mysterious about it, and is easily explainable.

The same cannot be said when the symptom follows a more or less long time after the emotion. It cannot be explained by spasm, for that would not last so long; again, vascular paralysis which allows the vessels to become distended, only produces a momentary lowering of pressure. Here it rapidly rises from repletion of the vessels. Other causes must be sought for. Now, if one study attentively the cases where the icterus appeared later, one will observe that between the casual emotion and the consecutive icterus the patient presented symptoms of gastric disturbance, loss of appetite, diarrhœa or constipation, headache, pain in the limbs and malaise.

This condition brings about an icteric state from infection of biliary passages, from consecutive tumefaction of the mucous membrane of the ducts even sometimes by production of a mucous plug at the point of entrance of the common bile duct into the duodenum.

But, how is it that an emotion may give rise to a gastric disturbance? This is a fixed fact and you know that prolonged chagrin often causes a loss of appetite; that fear may induce a diarrhœa, etc. An explanation of these facts is a very delicate task. The nervous system affects the movements of the digestive tract, at one time it may accelerate, at another render slow; thus it regulates the circulation and even the secretions of the intestines. Now, the gastric disturbance which produces the icterus is an infectious process, a fact which Chauffard has emphasized. It often appears as an epidemic, local epidemics, domiciliary epidemics. At other times the season exerts a manifest influence. What relation can there exist between an emotion and an infection? Here we return to the astonishment which physicians experience at the beginning of their bacteriological experiments. The relation actually exists and is to be explained. The intestinal tract is filled with injurious substances and microorganisms ready to invade the system; but, during the normal state, the intestinal glands, the bile ducts and the bile itself are aseptic. This condition of things is subject to modification. The glands and ducts may become infected. It seems that the more abundantly a gland secretes, the less liable it is to microbic invasion. Now, the secretions are regulated by the nervous system and this same system may prepare the way for infection. I have, unfortunately, no case in point to cite you, yet this hypothesis appears to me quite rational. As to the biliary passages, they are kept normal by the profuse flow of bile, for the quantity of this fluid which traverses them in twenty-four hours is not less than the quantity of urine which passes through the kidneys at the same

time. The bile itself is antiseptic. Rendu has recently given us a curious example. A patient presented grave hepatic symptoms which led one to think an abscess of the liver present. At the necropsy multiple abscesses were found in the liver, but they were aseptic. The biliary passages were filled with streptococci, but they were inoffensive. Both the inoculations and the cultures remained sterile. Hence the bile may render microbes sterile. Yet this antiseptic property is not always the same. You thus can see how an emotion may be followed by no effect or the very contrary. By transitory and mechanical modifications in one case; by an infectious process in an other. By symptoms limited to the stomach and intestine in one series of cases, while in others they extend to the biliary passages and are followed by icterus.

Again, you see how the prognosis is not always the same. Instantaneous icterus of emotional origin, ordinarily, lasts for five or six days. I know of no case of primary emotional icterus which was followed by severe results. But it is not the same in catarrhal icterus, for a secondary emotional icterus acts quite like the catarrhal variety. In certain cases the two influences are combined and the primary icterus continues as a catarrhal form; this latter may become serious. Examination of the urine in these cases is of considerable importance, for it indicates when the bile ceases to pass over into the blood. In our patient, the color of the stools indicates that the bile is being poured into the intestine, but, the presence of biliary pigments in the urine shows that a certain portion is actually taken up by the blood, and the patient is not yet convalescent. That forms one of the important elements in prognosis. But the state of the kidneys should be especially watched for albumen, and a large quantity of casts are met with in a great number of these cases. A diseased condition of the kidneys is always, in these affections, a source of danger from insufficient elimination of the waste products of the organism. Emotional icterus only becomes serious in those patients whose kidneys are affected beforehand. Catarrhal icterus, as a rule, does not last long enough to cause secondary alterations in the kidneys. Treatment will vary as the icterus is primary, or secondary to gastro-duodenal catarrh. Primary icterus will cure itself if the patient is in a tranquil state of mind. At the hospital, the mere fact of their entering and the consequent repose are sufficient treatment; in city practice one should be on the watch for exciting causes and to remove them. Emotional secondary icterus is treated by laxatives, especially castor oil, and exclusive milk diet. This form of diet diminishes considerably the number of microbes in the digestive tract. But in some patients the digestion is faulty and fatty foods are especially badly assimilated. Here an association of pancreatine with the other measures will render great service.

MEDICAL TUBERCULOSIS.*

HUGH HAMILTON, M. Sc., M. D., Harrisburg.

Medical tuberculosis is limited by the exclusion of those cases which by surgical interference can be relieved.

Presuming that the constant factor of tuberculosis is the bacillus tuberculosis, its bacteriological determination is essential for the diagnosis of the disease. Having now indicated the field of the subject, it becomes easy to discuss briefly the several forms that demand treatment. The almost invariable presence of the bacilli in those afflicted with phthisical complaints makes one wonder if the bacillus tuberculosus is the universal cause of this fatal condition of the human organism. The system is effected with more or less rapidity not always in accordance with the physique of the individual.

The studies of Koch brought out an immense amount of information, although his original purpose was frustrated and his benevolent hopes unrealized, yet the publication of his postulates stimulated extensive and active research with sure

* Read before Medical Society of the State of Pennsylvania, 1894.

principles upon which to formulate methods of treatment. A digression is made at this point into some of the effects of bacteriological growth and products. The simple growth of vegetation requires heat and moisture. The fungi bacteria require heat and moisture. They secure it at the expense of the normal physiological function that necessarily produces pathological physiological performance. This pathological condition is noted by irritation that shows its presence by sensitive degrees of febrile movement.

The alteration of the albumin present in the body into forms (chemical formula), which before the introduction of germs (bacilli) were inoxous, become through its parasitic existence, toxic—even to the bacterium itself. The object of germ life is to perform a vital cycle—probably best illustrated in vinegar, which live in great numbers in cider, by the germs and by their presence and animation change the saccharine material, through the alcoholic, to the acetous fermentation.

The process of making bread by yeast is another familiar illustration of this fact, stopped in its process by baking heat. Domestic wines are made this way, by stopping the fermentation in the alcoholic stage. Now observe that both *vinegar* and *alcohol* are antiseptics, preserving from decay vegetables and flesh.

Now the product of certain bacteria are *indol* and *phenol*—"antiseptics" we call them—should they in their cycle of living produce these by-products beyond the normal, they would cease their active career, provided no new albumins were offered for their consumption.

The *Tuberculin* treatment of tuberculosis disturbances in the coarser tissues was to a degree successful. Was it because those muscular tissues were firmer and changes in them slower? The application of these by-products locally in lupus, etc., had singularly fair results. In the lung tissues of a finer and more delicate character, it was impossible to reach the nidus of disease without also exciting an intense influence upon the general system. Whether the balance of the by-products to the life of the bacilli in lupus was so disturbed as to destroy the bacillus tuberculosis, remains beyond my ken—but it is a thought.

An alga in water previously used by an alga dies from its constantly used supplies of nourishment, and the excretions or by-products of its existence. Analogically, an animal would die in a closed vessel from the inhalation of his own exhaled carbonic dioxide—a by-product.

The art of Japanese horticulturists that produce dwarf, undeveloped fruit trees is well known. Can we stunt or stop the growth of these parasites by cutting off their supplies? We have succeeded in surgery to such an extent that the continuity of healthy tissue is separated and repaired at pleasure by following the simple rules of modern surgical practice. There is no pus in pure surgical interference. "Healthy pus!" who ever hears that phrase now?

Strumpel, measuring the irritation in consumptives, from the febrile movement observed in thermometic records, divides them into five classes:

CLASSES.	MORNING.	EVENING.
I. Sub-fever	N	100.4 to 101.3° F.
II. Hectic intermitt.	N+	101.3 to 104.
III. Remittent	100.4-101.3° F.	103.1 and upward.
IV.	Continuous	Fever.
V.	Irregular	Fever.

When we change the climate by altitude or latitude, *i. e.* returning the individual to his geographical place, we allay the ravages of the bacilli for a time.

We attempt and succeed when we send persons to the dry Colorado plains or the altitudes covered by balsamic pines. Where these are not possible, the application of the several essential (odorous) oils or their acid derivatives inhaled regularly, with generous diet and discipline of the general habits, we find an average rising from 50 to 80 per cent. benefitted and have their lives prolonged. The United States is rich in varieties of climate suitable for persons with pulmonary disease.

Respecting the contagiousness of tuberculosis there can be no question. The German police ministry promulgated detailed orders in 1891, which have been copied; and we are now agitating the populous cities of New York and Philadelphia to adopt them. The enforcement in Germany of this proclamation has already attained gratifying results; and the next twenty years will testify to its great wisdom. Compulsory vaccination has almost eradicated variola from the schedule of the national calender diseases of Prussia.

To sum up this matter:

1. Bacteriological diagnosis of the disease is essential.
2. The pathological process offers inducements of success in germicidal local treatment—which has succeeded so efficiently in modern surgery.
3. That the febrile movement should be diligently studied, both without and with active treatment, as insisted upon by Strümpel.
4. That climatic and sanitary conditions are necessary in the *whole* individual.
5. That every effort toward preventing the dissemination of *dried* sputum should be used.

TRANSLATIONS.

THERAPEUTICAL SUGGESTIONS FROM FOREIGN JOURNALS.*

RECTAL INJECTION FOR DYSMENORRHŒA.

Dr. C. von Rokitansky (*La Semaine Mèdicale*, No. 48, 1894) recommends as a useful measure, the following rectal injection in dysmenorrhœa:

℞ Extr. Opium..... o | 05 (gr. ¾,)
Powdered Camphor..... o | 30 (grs. v.)
Yolk of One Egg.
Water.....150 | o (℥iv. ℥v.)

Sufficient for one injection.

GLYCOSURIA AFTER CHLORALAMIDE.

Dr. C. Manchot (*Hospitals-Tidende* No. 26, 1894) has for a year examined the urine of all delirious patients at the Hamburg-Eppendorf Hospital, who received chloralamide in doses larger than three grams and whose urine was before free from sugar. In 214 cases there were 54 whose urine contained sugar. Out of 76 who received six grams a day the urine of 6 contained sugar; in 45 out of 135 who took nine grams, and in 2 patients who received twelve grams, per diem. The sugar persisted in the majority of cases from one to three days, once nine days, while sometimes it only lasted for a few hours. The quantity varied, but a combination of the fermentation and polarization tests found in twenty-one of thirty-six carefully examined cases, 0.2 to 0.5 per cent.; nine times up to 1 per cent.; five times 2 per cent.; once 2.2 per cent.; in one single case five per cent. was discovered. (352.8 grams, per diem). This patient has received six grams a day and had glycosuria for three weeks but recovered completely. Patients who had once presented glycosuria after the drug were easily liable to suffer from its repeated use; yet others on the contrary were free. Therefore there must be an individual predisposition. All these patients were alcoholists. Experiments on rabbits demonstrated that a daily dose of two grams would give rise to transitory glycosuria.

SUBLIMATE IN DIPHTHERIA.

Dr. Raubitschek (*Norsk Magazin for Laegevidenskaben*, No. 1894.) advises, in the treatment of whooping cough, the local application of 1 per cent. solution to the base of the tongue, tonsils and fauces. A tuft of cotton is dipped first into the solution and the fluid pressed out at the root of the tongue so that it runs down over the epiglottis and adjacent parts. In ordinary cases the proceedure may be repeated every other day, in grave cases every day. In fourteen cases where this method was tried, including three of his own children, of two to eight years, rapid improvement and a cure followed in a few days. There is no danger of poisoning. (?).

FALLING OUT OF THE HAIR AND TRICHOPHYTIASIS.

Dr. Brocq (*Le Progrès Mèdical* No. 16, 1894) recommends in falling out of the hair and trichophytiasis, the following prescription:

℞ Carbolic Acid,
Chloral,
Tr. Iodine, āā..... 100 | o (℥iij ℥j)

Apply locally every week once, in falling of the hair; in trichophytiasis, three or four times a week.

*In charge of the Translator, F. H. Pritchard, A.M., M.D.

TREATMENT OF THE OBSTINATE CONSTIPATION OF CHRONIC TUBERCULOSIS OF THE PERITONEUM, INTESTINES AND MESENTERIC GLANDS IN CHILDREN.

Dr. Th. Escherich (*La Semaine Médicale*, No. 47, 1894) speaks highly in the treatment of the associated chronic constipation of chronic tuberculosis of the peritoneum, etc., in childen, of the following formula :

℞

Sulphate Atropine..	0	003 (gr. 1-20).
Water.....	100	0 (℥iij ℈j).
Gum mixture	20	0 (℥v).

A teaspoonful twice a day.

To obtain the desired effect this mixture should be continued for a long time; if necessary, it may be associated with a purgative. It is a matter of course that during its administration the pupils should be carefully watched.

TREATMENT OF TAPE-WORM IN ADULTS.

Dr. Léméré (*Le Mercredi Médical*, No. 32, 1894) praises the following formula in the treatment of tape-worm in adults :

℞

Ethereal Extract Male Fern	6	0 (℥jss).
Calomel.....	0	60 (grs. ix).
Distilled Water.....		
Gum Syrup.....	16	0 (℥iv).

Powdered Gum Arabic q. s. to form an emulsion.

To be taken at one time, in the morning, shaking well before taking. Keep the patient absolutely quiet and on a milk diet for twenty-four to thirty-six hours before its administration.

The worm will be expelled, without any disagreeable sensations, in thirty to thirty-five minutes after taking the remedy.

In children of six to twelve years the dose is four grams (℥j) of the extract of male fern and forty centigrams (grs. vj) of calomel.

TRAUMATIC EPILEPSY CURED BY IODO-MERCURIAL TREATMENT.

Dr. Dougall (*La Semaine Médicale*, 47, 1894) has obtained a complete and definitive disappearance of epileptic attacks of traumatic origin, in a child of twelve years, by the following formula:

℞

Sublimate.....	0	12 (gr. j¼).
Iodide Potash.....	7	50 (℥vj grs lij).
Infusion Gentian.....	180	0 (℥v)

One teaspoonful after each meal.

For ten days the child took three teaspoonfuls every day, after which the dose was doubled. A cure was obtained in six weeks.

DIURETIC AND HEART TONIC FOR CARDIAC INSUFFICIENCY.

In the *Revue Internationale de Bibliographie Médicale*, No. 11, 1894, the following formula is offered as an efficient diuretic and heart tonic, in cardiac incompetence:

℞

Infusion Juniper.....	300	0 (℥xj).
Acetate Potash	250	0 (℥ viij).
Powdered Digitalis Leaves	60	0 (℥j¼).
Powdered Squills	30	0 (℥j)
White Wine.....	240	0 (℥vijss).
Rectified Alcohol.....	30	0 (℥j).

To be taken by the dessertspoonful.

AN ANTIDOTE TO HYDROCYANIC ACID.

Dr. J. Antal (*La Semaine Médicale*, No. 48, 1894,) states that the nitrate of cobalt is a very efficacious antidote to hydrocyanic acid. In a watery (½-1 per cent.) solution it has the advantage not only of neutralizing the acid in the stomach, but also that in the blood. Even if taken in large quantities is absolutely harmless. This salt of cobalt is eliminated from the organism as rapidly as it is absorbed from the stomach. In case of poisoning by this acid he would advise, basing himself upon experiments on dogs and rabbits, subcutaneous injection of twenty to thirty ccms. of a ½ per cent solution of the cobalt salt, while it may be drunk by the glassful.

APOCYNUM CANNABINUM IN HEART DISEASES.

Dr. Glinski (*Gazzetta Degli Ospedali*, No. 82, 1894,) by experiments on animals has found that the root of apocynum cannabinum contains a violent poison, which, in large doses, paralyzes the heart, and, in small quantities retards and strengthens its beats. Basing himself on these results he experimented upon himself, for he suffered from hypertrophy of the left ventricle, with intercurrent attacks of dilatation of the heart, mitral murmur, dyspnœa, etc. He then took fifteen drops of the fluid extract, three times a day. Having observed that all of his symptoms disappeared in two days, he experimented on other cases having palpitation and disturbed compensation, where strophanthus and adonis vernalis were without result and digitalis seemed contraindicated. He reports the details of his cases and concludes as follows:

1. Apocynum cannabinum root appears

to have an action similar to that of digitalis, without cumulative action.

2. In cases of dilatation apocynum rapidly diminishes the area of dullness.

3. It increases the quantity of urine, causes the palpitation to disappear, and promotes the absorption of exudates.

4. Beyond a sensation of increased pulsation in the arteries of the head, he has observed no disagreeable effects.

It may be used as a decoction, three or four spoonsful a day; the tincture (1:40) five to ten drops, three or four times a day; or, the fluid extract, in a dose of ten to fifteen drops, three times a day.

ERUPTIONS FROM IODINE.

Dr. Szadek (*Gazzetta Degli Ospedali*, No. 82, 1894,) distinguishes five forms of iodic eruptions: the erythematous, the papulo-pustular, the bullous, the tuberous and the hemorrhagic.

The erythematous form is characterized by extensive desseminated areas in various regions of the body, particularly on the forearms. If the iodine be continued it may become transformed into the papular variety, which, with the pustular eruptions, is usually observed on the face and scalp; it greatly resembles that following the bromides, except that the confluent form is very rare.

The bullous variety is observed as large disseminated bullæ upon the head, face, neck, extremities and trunk. If the drug be continued, and especially in large doses, the bullæ takes on a purple-reddish color, and become filled with sero-pus, mixed with blood.

The tuberous form is not different from urticaria and erythema nodosum, but it is more striking and less circumscribed in large and elevated nodes. It is localized chiefly on the head and lower estremities. This form sometimes passes over into the ulcerating variety.

The hemorrhagic form as a rule is not severe and is situated upon the legs. Generally, it develops at the beginning of the treatment and it may follow small doses.

The writer has observed two peculiar cases of iodic exanthem. In one the eruption consisted of large and disseminated elevations and bullae, upon the extremities; in the other hemorrhagic exanthem was produced by small doses of the iodide and was upon the trunk and extremities. The variability of the iodic eruptions renders their diagnosis difficult. All the lesions usually disappear a few days after discontinuance of the drug.

TREATMENT OF OBESITY BY THYROIDIN,

Dr. Yorke-Davies (*Hospitals-Tidende* No. 32, 1894,) in a number of patients under treatment for obesity, where the usual measures were unsuccessful—exclusion of fatty and increase of nitrogenous foods—treated them with the extract of thyroid glands. He administered three tablets a day, with the following result: One patient, who with dieting alone, only lost two and three-fourths pounds, under the thyroid extract, in two months lost twelve pounds. Another lost with diet alone, in one month, three and a quarter pounds; under the extract, in six weeks, nineteen and one-quarter pounds. A third lost, in a month, six pounds; under thyroid treatment, in the same time fifteen pounds. A fourth, in three weeks six pounds; with thyroid extract, in the same time, twelve pounds. A fifth, in two months, with dieting fifteen pounds; in three months with thyroidin, twenty-seven and three-fourth pounds. Finally, a sixth patient, with diet, in two months, fourteen pounds; with thyroid extract, in a month, eight pounds. (Dr. Dale James *British Journ. Dermatology*, June, 1894, has reported glycosuria with nervous depression and frequent attacks of cerebral congestion, after the use of thyroid extract in an inveterate case of psoriasis: Polyuria has also been frequnetly noticed.—ED.)

Cutaneous Absorption. (Fubini and Pierini.)

The various experiments done by the authors goes to show that the healthy skin does not absorb non-volatile substances. After an immersion of both arms and forearms for half an hour in five per cent. solutions of sodium salicylate, and five per cent. solutions of potassium iodide, the urine contained neither salicylic acid nor iodide. The posterior extremities of guinea pigs were immersed for one hour in a two per cent. solution of nitrate of strychnine and a 1 in 400 solution of sulphate of atropine without strychninic symptoms, and without mydriasis.—*Canadian Practitioner.*

EDITORIAL.

PRIVILEGED CONFIDENCES.

Judge Cole, of the Supreme Court of the District of Columbia, recently rendered a decision holding that physicians and lawyers, when called upon in court, are not exempted from giving testimony on the ground that such information was professionally confidential.

Think of it! A learned judge compelling the violation of sacred honor, to obtain, forsooth, some evidence in a *divorce suit*. The subject will bear consideration.

The usefulness and good repute of the physician is based upon his worthiness of trust, the care with which he keeps his own counsel and the secrecy with which he preserves the confidences of his patients. No matter what may be his technical skill, if the physician fails in that good faith which preserves inviolate those communications made by his patients in all confidence, and which are indispensible to the performance of his professional duty, he will lose his good name and usefulness in the community in which his work lies, and will be disqualified for successful work in the profession in which trustworthiness and the keeping sacred of confidential communications is the one potential factor of success.

The extent to which these communications are and should be privileged by law, is of interest to the medical profession.

At common law, information given in confidence by the patient to a physician is not privileged; but in various States communications made by a patient to his physician or surgeon, and information acquired by him while attending a patient in a professional capacity, and which were important to enable him so to act, are protected by statutes. The privilege extends to facts necessary to enable the physician to prescribe. Such facts are privileged whether learned directly from the patient himself or acquired by the physician through his own observation or examination.

The object of these statutes seems to be to place the communications made to physicians in the course of their professional employment, upon the same footing with communications made by clients to their attorneys in the course of their employ-

ment. They protect with the "veil of privilege whatever, in order to enable the physician to prescribe, was disclosed to any of his senses, and which was in anyway brought to his knowledge for that purpose." Whenever evidence comes within the purview of these statutes, it is absolutely prohibited. Death does not remove the seal of secrecy from the communications and disclosures which the patient makes to his physician.

Until protected by statute, courts cannot exercise judicial power in forbidding the disclosure of confidences held secret by physicians.

In criminal cases the law is not well settled. In some of the States, as in California, the provision is expressly limited to civil cases. In New York the privilege of such confidences is extended to criminal cases. The following New York Supreme Court decision is one accepted as authority in that State and is frequently quoted in interpretation of the statutes of other States. In this case the Supreme Court (Landon, judge) gives the history and the law governing in the case as follows:

"On the night of the 18th of June, 1888, the defendant called upon Dr. Crounse, a person duly authorized to practice physic and surgery, and employed him to attend Mary A. Brower. The defendant was urgent. The doctor testified that upon coming into his office the defendant said:

"For God's sake hurry up, my wife has a fit, or fainted or something, I don't know what." He said: "Probably you would like to know what the difficulty is before you leave the office."

I said, "Yes, it might be a help to me because I might need something that I would not take with me."

He said, "This lady down to the house I am living with, I am not married to, but expect to get a divorce from my other wife and get married. This lady is about three months gone in the family way and she introduced a catheter, with a wire, in her womb, and after she had introduced it far enough to hurt her, I blew in it.

I said, "What did you blow in it for?"

"I done it before and it worked all right."

The doctor found the patient in a dying condition, and she died in about half an hour.

Two physicians who made the autopsy, testified that, in their opinion, the woman died from shock caused by the injection of air into the uterus. Aside from the testimony of Dr. Crounse there was no evidence tending to connect the defendant with an operation to procure miscarriage."

In rendering a decision in this case the Court said: "The defendant employed the physician to try and save Mrs. Brower's life. His alarm and anxiety were great. He knew what had taken place, and suspected that it was the cause of her sudden prostration, and felt that the physician ought to know it and to govern his treatment accordingly. The physician did want to know. In this critical moment, with the sole purpose of saving the woman's life, he disclosed the secret to the physician to make him to act rightly. To have withheld the disclosure would have made the defendant a consenting party to the woman's death. We have no doubt that the statute, both in its letter and spirit, protects the confidence thus reposed in the physician and forbids him to betray it."

With this testimony stricken out there remained practically nothing to sustain conviction.

The strict construction by the court of the statute would seem in this case not to have served the ends of a strict justice. Carefully studied in all its bearings the wisdom of the decision is clear. As human affairs run no statute, no matter with what wisdom framed, can meet all

and every exigency or be free from certain ultimate evils.

Many of the States, Pennsylvania among them, are without such a statute.

The greater portion of our legislation is the work of lawyers—they are the framers of our statutes, and they follow but a very natural human tendency when they frame them in the interest of their profession. Unfortunately the extent of this character of legislation is not limited to privileged communications. There is better logic, there are more sound reasons of public policy in support of privileging the communications to physicians, than can be advanced for the protection of the confidences of client and attorney. Not but that they too, for very strong reasons of public policy, should be privileged.

Aside from reasons of *policy*, there are the strongest of *ethical* reasons that the confidences between patient and physician should be protected. The relation of physician and patient is a peculiar one, and, from its very nature, requires absolute confidence. He is the trusted custodian of individual and family secrets and he cannot without breach of high moral obligation divulge them. The law should not step in and unseal his lips and force him to give information gained in the privacy of the sick room and under the stress of disease. If in exceptional instances such information promotes the ends of justice, as a rule it works mischief and injustice.

In this connection the example set by the Legislatures of a number of the States is a good one. It is but simple justice to physicians and surgeons that these confidences, which are inseparable from their very relation to their patients, should be respected and protected by the law. If such a law is in accord with sound public policy and serves the ends of public justice in the great state of New York and in other States, it would do same in Pennsylvania. The information gained by the physician from his patient is needed for the intelligent discharge of his duties, is given in one of the most intimate of human relationships, and the law should forbid its being heralded to the world by being testified to in open courts and spread upon public records. It is not a matter that can safely be left to the discretion of courts, however enlightened many of them maybe in the equities, the principles of public policy and justice, and the proprieties and ethics of the profession. Such practice multiplies conflicting precedents and leads to the confusion, rather than the simplifying of the law.

There is no class of men in any of our communities who do more to protect society against the wicked and forbidden practices of the depraved and criminal, than do physicians. They have an interest in the moral welfare of communities as well as in the physical health. Moral disease, with its contagions, comes as close home to them and their families as to others of the community. Therefore it is no argument that protecting the confidences between the physician and his patient would tend to shield crime.

The confidences existing between the physician and his patient have as strong grounds, as logical reasons for legal protection as privileged confidences, as have those existing between the attorney and his client, and there is nothing our law makers would so strongly and bitterly resent as a betrayal of the confidences *they* are forced by conditions to repose in their physicians. Such exposures would blast many a political career.

ABSTRACTS.

NOURISHMENT IN ACUTE AFFECTIONS.

ALFRED K. HILLS, M. D., New York.

If we would succeed in the treatment of diseases in general, we must take into account the fundamental principles upon which all organic life must depend, viz., the pabulum upon which the tissues are fed, and the varying circumstances under which the functions are affected by the various elements known as foods.

In our daily practice we are constantly met with the question: "What shall we give the patient to eat?" and its solution is sometimes a difficult one.

Naturally, the patient, the friends and the nurse all look to the physician to give explicit directions as to what articles of food are proper in a given case, just how it shall be prepared, and the frequency with which it shall be administered.

The form in which we shall offer nourishment to our patients acutely ill is of the first importance, after deciding as to the kind required in the particular case, and its suitable preparation is next in consequence.

It is absolutely necessary that the physician should not only be able to select the kind required, the form in which it should be exhibited, but he should also know how to prepare it, and be able to give intelligent directions to a suitable person to perform this service in a manner acceptable to the patient, who may be whimsical and difficult to please.

It does not matter particularly how we may classify our articles of food, so long as we bear in mind that *water* is of prime importance in the restoration or maintenance of organic function, and that salts, fats, sugars, starches and albuminoids must come into the account and receive that careful consideration necessary to the individualization imperatively demanded for satisfactory results.

It is an easy matter to generalize, and even to form classes, but it is oftentimes a most difficult matter to individualize cases for the purpose of treatment,

If we stop to consider the physiological fact that the human body is two-third water, and that this ratio must be maintained for healthy functional activity, it stands to reason that any variation from this standard must be at the expense of the solids of the body. Many cases of disordered digestion are due entirely to lack of sufficient water. Physiological experiment has demonstrated that mormal digestion in a healthy organism requires a pint of water in some form with each meal, and that any variation from this rule will be at the expense of the digestive powers. The majority of people are better off for water between meals when in health, and while there is no danger from taking water in large excess, at the same time it is hardly worth while to augment the bulk of the body to such an extent that it becomes burdensome. Of course we should not overlook the importance of intense thirst as a symptom of diabetes, and treat it accordingly.

In acute affections it is better to flush the intestinal canal with water, hot or cold, according to indications, and I know of no precautions in this respect which should be exercised. Water not only helps to clean the stomach of its contents, and aid in the digestion of food, but when taken up by the blood vessels, aids in normal nutrition and removes effete matter from the circulation by increasing the mobility of the fluids, thus relieving congestion of important internal organs.

The refreshing draught of fresh cool water should not be withheld from our parched fever patients under any circumstances, and they should be even urged to increase the quantity. The physician should see that it is offered, whether it is asked for or not, in all cases.

In cases of acute catarrh of the stomach, there is no agent which gives so prompt and durable relief as water, sipped as hot as it can be borne, and this will apply in a great number of affections, especially where the stomach is irritated in this way. Hot water quenches thirst better than cold, but we should bear in mind that it is an excitant.

It will not do attempt to substitute

alcoholic stimulants, tea, coffee, or even milk, for pure water, as they will serve in place of this important agent.

Our female patients may be induced to take more water it we convince them that rotundity of the body depends upon a suitable quantity of water, and that the blood vessels, when kept filled with a sufficiency of this fluid, will retard the wrinkling of the skin, which is the bane of every woman who cares for her personal appearance. We should, I think, impress upon our patients the fact that healthy function, not only as regards digestion, but in respect to all other functional activity, absolutely depends upon the water ingested.

There is no drug which will act more effectually—and certainly the action is more kindly—than water, in those acute affections where the liver is torpid, bowels inactive, tongue heavily coated, etc.; but the quantity ingested must be large, sometimes enormous, and in some cases as hot as it can be borne. Even when the liver is overactive, there is no remedy which so favorably clears out the bile and hastens convalescence as water, and there can be no unfavorable reaction, as there may be when drugs are used for this purpose.

I am confident that the kidneys, the great sluice-way of the body, may be saved from serious consequences, in many cases, after acute illness, especially in scarlatina and other exanthematous affections, by the free and methodical use of water internally.

We are often called upon to treat cases of nephritis in its various forms, in which the primary lesion was in the liver, which would have been prevented by the timely and proper exhibition of this simple remedy, and I know of no means which act so favorably, even in the advanced stages of the disease, washing out the life-destroying urea, and preventing or mitigating the terrible convulsions, which so often result in consequences so painful to witness.

Let us therefore bear in mind that the body needs cleansing internally as well as externally, and that there is no agent equal to *pure water* for this purpose.

The various mineral waters, of which we have a great number, should be studied for their specific individualities, and prescribed in accordance with this principle.

Of the artificial mineral waters, I know of none which are so satisfactory, reliable and trustworthy as those made by the well-known house of Carl H. Schultz. The water used in their manufacture is distilled, the formulæ are exact counterparts of the natural waters, they are fully charged with carbonic acid gas, and are in every respect just what they claim to be. I am justified, I think, in commending these waters to you, since I have used them to a large extent for more than twenty years.

The individualization of articles of food as respects the disease we are treating is important, and we should also carefully consider personal idiosyncrasy in our selection, as the great variety of foods at the present day, of more or less nutritive value, enable us to do. We find, however, that iron-bound rules respecting these matters will not answer practically, but that an enlightened intelligence must be used in all cases.

We ought always to keep in mind, in prescribing the diet for our patients, the modern physiology of digestion, as it appears in the light of recent investigation.

I often find that stomach indigestion is caused by insufficient mastication, the great majority imperfectly performing this act, so that the stomach is taxed beyond its power in the process of disintegration of those articles of food which should be hydrated at this point, thus throwing, perhaps, the work upon other organs which would be done here if the act of mastication were properly performed.

We ought also to bear in mind prescribing pepsin, that an acid medium is required for its activity, that it should never be combined with an alkali, and that hydrochloric acid should sometimes be added.

If we stop to recall the fact that starches should be digested by the salivary secretion, we will realize not only the importance of thorough cooking of articles containing starch, but also the necessity of allowing sufficient time in mastication for the mass to become properly intermixed with the saliva necessary to digestion.

Acute intestinal indigestion is often due to faulty mastication of foods containing starch, or which have not been sufficiently cooked to admit of their easy digestion. While we may be sufficiently conscious of the fact that all food must assume the soluble state before it can be taken up for assimilation, I am confident that we shall

find that the great majority of our patients do not accomplish this result.

The habit of rapid eating, hence faulty mastication, is a more important element in the cause of many diseases than is generally supposed. I have found that I get on much better in the treatment of patients since I realized the importance of mastication, and I try to convince them of this fact by explaining its physiology in a way which they can understand, as I find they are more likely to overcome the habit—not an easy thing to do—it they understand the reasons which underlie the subject.

Patients acutely ill will tolerate fats only when presented in the most delicate forms, such as cream-vichy, the yolk of egg with vichy, or vichy and milk. Sweet, fresh butter is an excellent form of fat when it is tolerated by the palate.

Cane and beet sugars must be inverted by the addition of a molecule of hydrogen before they can become as soluble as grape sugar and maltose, hence, they are more difficult of digestion than the lower forms of sugar, and should be used sparingly, if at all, as they are subject to acetous fermentation, which is irritating.

Grape sugar, milk sugar, and maltose are the ideal foods in this line, as they are easily soluble and readily absorbed.

Milk sugar, which is subject to lactic acid fermentation, is greatly to be preferred in the diet of the acutely ill, to cane sugar, which gives an acetous fermentation, for reasons which are obvious. For this reason I have suggested that milk sugar should be used in the preparation of kumyss, a point which some manufacturers have promptly utilized with great satisfaction.

Grape sugar, which is so important and useful in the treatment of the acutely ill, can now be obtained in a concentrated, unfermented form, without having been boiled, and absolutely free from any extraneous preservative whatever, from the California Grape Food Co., of Los Gatos, Cal., or from druggists generally. This grape juice is a great boon in the sick room, and is furnished in two varieties—red Zinfandel, not very sweet, and white Muscatel, having the well-known properties of this delicious grape.

It may be combined with various agents for use, but it is especially delicious with clysmic, vichy, or other mineral waters.

Grape juice, a compound of water, sugar (chemically dextrose), acids, salts, etc., exhibits all the proximate principles required for nourishment of the human body, resembling milk.

Grape sugar, the final physiological form of all starch and sugar, thus represents the simplest nutrient of its class for assimilative purposes, and we should take this fact into account when prescribing starchy foods, potentially sugar, and which must be converted to grape sugar before they are taken up, by taxing the digestive functions of Brunner's and Lieberkuhn glands for twelve to twenty-four hours or more.

Persons acutely ill oftentimes secrete very little saliva, so that starches are acted upon but slightly, if at all, and then grape sugar or glucose, in some form, is imperatively demanded. The grape, as an article of food in these cases, is excellent; but in the grape juice, as prepared, we have always at hand, in a most convenient form, all the qualities to be obtained from the grape itself, and at a reasonable price, which, at certain seasons of the year, is an item of importance to some.

I am in the habit of using syrup of glucose in place of cane sugar in many instances. I can see no harm in the artificial conversion of starch to glucose, by means of sulphuric acid and lime, so long as we are given a pure article. In commerce it may be obtained in its pure state as a syrup, or with dextrine, as desired, when it will appear in a sold state, and is furnished in cakes. The syrup is not as intensely sweet as cane sugar, and it requires more, of course, to be used for sweetening purposes, to satisfy the palate, but it is easier of digestion, accomplishes better results, and is less liable to produce indigestion. I add a teaspoonful or more, as desired, to a glass of milk, or any other vehicle, and, as a rule, patients are satisfied with it, and never any unpleasant results follow.

In acute affections the various fruits are refreshing, and give variety, according to individual idiosyncrasy, and are useful, not only for the water they contribute, but for the sugar, citrates, malates and tartrates of potassium which they contain in varying proportions, all useful under certain circumstances and conditions. Grapes certainly stand first in food value, not-

withstanding the fact that the banana* is the more nutritious, but the latter is much more difficult of digestion, and should be allowed with caution.

Figs and dates contain sixty per cent. sugar and six per cent. albuminoids, and are valuable as foods when indicated.

In the class of starchy foods we have a great variety to choose from, depending upon what we wish to accomplish, and upon the palate and digestive power of our patient. We have numerous prepared foods, of which Mellin's is a good example, for use where the digestive powers are impaired. Arrowroot makes a bland mucilaginous food, which, when combined with milk, answers a purpose, when the more pasty starches would not be tolerated.

Steamed rice with plenty of milk makes an excellent food combination, and a baked potato which is mealy, with plenty of salt to offset the potash which the potato contains, are both good forms of starch. Gruels made with the various cereals and combined with milk, or with diluted cream, as the case may require, are excellent foods for the acutely ill. Of course, it is necessary to individualize our cases for special purposes, but the most nourishing gruel for general use is made from the entire wheat.

Johnson's Educator Crackers, made with the entire wheat, either whole or powdered, according to circumstances, and eaten with milk or cream, make not only a nutritious dish, but are most agreeable to the palate of some.

Where more fat is desired, as the patient prefers, corn or oaten meal may be used for gruel, and the nutritive proportion can be augmented at pleasure by the addition of milk.

In the treatment of acute diseases we should not despair, but always bear in mind that death is a failure of nutrition, and that convalescence is more rapid where wasting is the least. Patients often drift into a critical condition simply from lack of proper feeding ; foods are given which are disliked or not tolerated, and we, as physicians, should find out the reasons for all these things, so that we may not have to look back upon a life lost through starvation!

The digestive powers are always impaired when one is ill, the ferments of the stomach may be powerless for digestion, and to pour in foods under these circumstances would be useless in the extreme.

The patient suffering from the shock of traumatism may not have that thirst which belong to the pyrexial state, so that drinks are not desired and solid foods not tolerated.

Under these circumstances, as a rule, a cup of beef juice or of peptones, repeated as required, will not only be tolerated, but will restore the lost equilibrium more hastily than can be done in any other way. It is much better to adopt this method than to wait for nature to do the work, as she is slow and extravagant, and often needs help in these reactionary methods necessary to the resumption of the ordinary diet.

In the treatment of our fever patients, no matter what the lesion, with the dry fauces, thirst and high temperature, the use of water becomes imperative, and if we can combine it with some nutritive constituents, the patient will be the gainer. We should bear in mind that milk is a food, and will not take the place of water in quenching thirst, It is well to dilute it with effervescing mineral waters, with or without the addition of grape juice. The starving of patients to keep down the fever is a thing of the past and should be utterly condemned.

A most refreshing and withal nutritious draught may be made with grape juice and effervescing mineral water, with the addition, according to indications, of either toast water, white of egg, yolk of egg, the entire egg, or of any of the extracts of beef, or of peptones, depending upon what we wish to accomplish.

I always include the grape juice as a base, when I can, for three reasons, viz.: 1. It is refreshing. 2. It answers the purpose of sweetening so much better than sugar; and 3. It is the normal nourishment of the body and is generally tolerated.

In some cases, other fruit juices, such as apple, tamarind, pine apple, fresh currants, orange or lemon, all of them of little nutritive value, may be used to bridge over or be added to the grape juice to suit the palate. Malt extracts are used by many for the maltose or grape sugar, soluble dextrine and some soluble albuminoids

* Nitrogenous matter, 4.820; sugar, etc., 19.657; fat, 0.632; cellulose, 0.2200; saline, 0.791; water, 73.960. N., 1–20; sugar, 1–5; water, ¾.

they contain, and their sweet taste may also be largely overcome by the addition of effervescing mineral water.

There is a difference of opinion in regard to the use of milk in enteric fever, not only on account of its deficiency of fuel food, but because the first step in its digestion is curdling, and a firm curd irritates. There are several ways in which the large curd may be avoided, and one of the best with unfermented milk is the addition of effervescing mineral water. Some use lime water, and others use baked flour. When the palate is not offended by an acid, kumyss may be used to great advantage, as here we find the curds small and that they will not become large in the process of digestion.

As I have said before, cane sugar is subject to acetous fermentation, and for that reason kumyss should be made with milk sugar as a ferment, as from this we obtain a lactic acid fermentation, which in many cases is greatly to be preferred.

The consensus of opinion is in favor of the free use of drinking water systematically in typhoid, either hot or cold, according to indications. As a rule, I prefer the carbonated, unless the patient objects. Many object to milk unless predigested, and all, I think, agree upon the use of kumyss, provided it is not disliked by the patient. Alcoholic stimulants are not indicated in all cases of typhoid, hence we should beware of prepared foods which contain whiskey. Glycerine with hydrogen dioxide is an excellent remedy, for many reasons which will be obvious to any one who stops to reason out the *modus operandi*.

In our cases of indigestion, acute or chronic, we have found papoid one of the best digestive ferments, and especially as it acts equally well in an acid or an alkaline medium. Papoid dissolves the abnormal mucous secretion, prevents fermentation, stimulates the gastric mucous membrane to normal secretion, beside being one of our most powerful solvents of all articles taken as food and certainly holds a large place in our armamentarium.

Milk sugar is claimed by some to admit of no direct alcoholic fermentation, but by a lengthy action of yeast, this may be accomplished.

When kumyss proves to be too heavy a food, and an acid is required, buttermilk which has been allowed to stand for a time in a warm place, and then cooled to the taste, will answer the purpose.

Buttermilk is as light a food as we can well provide, as it contains no fat, and but a small quantity of proteids, in the form of well-broken curds. The entire milk, or cream, or skimmed milk, should be selected according to circumstances, with or without effervescing mineral water.

In order that we may know just what is being given as food, the nurse's record should be carefully kept, so that it will always tell exactly what is being done; then, with a full knowledge of food values, and with the air to adapt food to suit conditions, we can have increased hope for recovery in all our cases.

We often find patients who assert that they cannot tolerate milk of any kind in any quantity, as a diet, and occasionally we have to admit that these claims are well founded. I think, however, that the majority can overcome this idiosyncrasy by judicious and methodical effort. Patients who dislike milk, or are disinclined to take it, should be carefully dealt with, and as a rule the prejudice (for many times that is all it amounts to), or the dislike, can be neutralized. The use of milk in these cases should be commenced gradually, and in small quantities, increasing slowly and methodically each day until the maximum is reached.

I have found the addition of grape-juice, glucose or maltine to milk, excellent aids with those who like sweets, in establishing the milk diet.

Milk will sometimes form solid curds in the stomach when used in its natural state, and may require the partial conversion of its casein to albuminoids, which will not coagulate.

This may be accomplished by a process of shaking in a closed vessel for a short time, by the addition of carbonated water, or by the use of peptonizing powders, which are furnished by the well-known house of Fairchild Bros. & Foster.

The process is well known to you all, but should the details have escaped the memory, directions will be found with the powders as furnished, and the degree of digestion may be limited by heat and cold to suit the particular case. Albumoses thus produced, non-coagulable by heat or by dilute acids, answer an excellent purpose in many

cases, but we should remember that when digestion it carried too far, a peptone is produced, with its bitter taste.

The subject of feeding with sterilized milk has not fulfilled in practice expectations of its sanguine advocates. Sterilized milk is said to be less easily digested than untreated milk, and that continued use is liable to be followed by scurvy, and that it is not prophylactic of septic diarrhœa. The reasons are stated to be that the milk is acid, and contains various products of decomposition which are poisonous and irritating to the intestinal mucous membrane.

It is positively stated upon good authority that boiled milk curdles within the stomach in the same way as if it were unboiled.

Sterilized miik deteriorates with time, and should not be used if more than a week old, kept in a cool place.

The albumen of egg forms an excellent food in various combinations in many acute affections. I have been in the habit of using it mixed with some mucilaginous medium, in cases of acute enteritis, with excellent results. Patients are able to take the whites of anywhere up to a dozen and a half, in twenty-four hours. All sorts of combinations may be made with it, depending upon conditions and circumstances. I often use it with grape juice and some effervescing water, to the great satisfaction of patients. It may be added to the cold beef extracts to great advantage, and in this way we obtain a most nutritious, as well as stimulating food, which is agareeable to many palates

Hauser (*Berl. Klin. Woch.*, Aug., 14. 1893.) proposes for infants a food consisting of cow's milk corrected by addition of cream, milk sugar and egg albumen, heated above 130°, with the result of checking vomiting and diarrhœa, and we should certainly keep the suggestion of adding egg albumen in mind, as our resources are sometimes taxed to the utmost to find a food which will agree with some infants.

I have pushed the egg to the extent of being able to detect it in the urine, a result which sometimes obtains. The egg albumen is much easier digested when mixed with some carbonated water. We should study differentially the use of the entire egg, the white and the yolk individually, and a wider range of application of this valuable food stuff will commend itself to us.

Nitrogenous food in some form or combination, is absolutely necessary to the continuance of animal life, beyond a short limit. The proteids, defined by Kirkes to consist of albumen, casein, gluten, and their allies, and gelatin, and which contain carbon, hydrogen, oxygen ,and nitrogen, and some of them sulphur and phosphorus, form, according to Foster, the principal solids of the muscular, nervous and glandular tissues, of the serum of blood, of serous fluids, and of lymph, and are frequently spoken of as albuminoids.

Proteids are readily converted at the temperature of the body into peptones by the action of the gastric juice in an acid, or of pancreatic juice in an alkaline medium.

Physiologically speaking, the whole animal body is modified protoplasm, the proteids forming the chief mass, fats and carbohydrates however, never being wholly absent. It is a self-evident fact, therefore, that our efforts in restoring health must be directed in accordance with sound physiological principles, and the pabulum necessary to restore a lost equilibrium must combine the elements necessary to nutrition in a normal manner. This, however, cannot always be done in the sick, by the exhibition of foods in what is known as a mixed diet. We are compelled sometimes to limit our food supply to any one of the class of elements which go to make up an ideal diet. We have heard much of late of albumose or albumen peptone, as a most desirable article of nutrition in certain conditions. Albumose is a term applied to partially digested albumen, just before the full change to peptone occurs, and it is considered a veritable tissue builder. Albumoses are odorless, tasteless, and are consequently devoid of some of the odjectionable features of the peptones. The most perfect preparation of the albumoses yet produced is furnished us from Germany, under the name somatose.

Somatose is a yellowish, fine, granular powder, readily soluble, perfectly odorless and practically tasteless, containing the nutritive qualities of meat, minus the glutinous material, fat, creatin, xanthin, etc. The usual dose of somatose is a teaspoonful or a dessert spoonful dissolved in a cup of milk, soup, grape juice, with or

without the addition of effervescing water. It has been found that this agent diminishes nitrogenous waste, replaces the albumen of the organism, and one part is equal to six parts of beef devoid of fat.

It is claimed to be indicated in all acute diseases where a food rich in albumen and readily assimilated is required, and I have found it of especial service in cases where the peptones were declined on account of their odor and taste.

We may imitate, artificially, the action of the stomach in converting meat albuminoids into soluble substances, for use in such patients as are unable to complete the act themselves, and thus add to our armamentarium for their treatment. I have used the beef peptones made by Rudisch for years, in enormous quantities, and I am confident I have saved many a life with them.

There are cases where the increase of urea is to be avoided, in which we should be cautious in the administration of beef peptones, the same as we would in allowing the meat to be taken in the undigested state. We should have positive indications for and against the use of meat, as we would any other agent. The healthy human stomach has no trouble in digesting beef that has been properly masticated, and when meat is indicated in the acutely ill, there can be no objection to a peptone made from the entire meat by means of artificial heat carried to a high temperature, which so entirely changes the fibrin as to make it correspond in general composition with other proteids, and, according to Schonbein, it becomes a bearer of ozone.

Beef peptones of this class contain some sixty per cent of nutritive value, and I cannot speak too highly of their employment in a great variety of acute affections when this form of nitrogenous food may be called for. I will not take the space to enumerate the great variety of affections in which they are useful, because it is well known clinically to most of us that beef peptones fill a large place in the nourishment of our patients suffering acute affections.

A characteristic feature of peptones is their extreme diffusibility, a property which they alone, of all the proteids possess, since all other forms of proteids pass through membranes with the greatest difficulty, if at all. (Foster.) In order that the peptone may not escape by the kidneys as easily as it gets into the portal vein, it is dehydrated and once more becomes a proteid.

The further study of the elaboration of the albuminoids, while of the greatest practical interest, would carry us too far for the limits of the present paper, notwithstanding the fact that many points have an important bearing upon the dietary and other treatment of acute cases.

It must suffice for us to say in this connection that the liver and kidneys require plenty of water, to successfully carry off the excess of soluble urea which is the result of taking albuminoids in excess of body wants.

The relative value of the various preparations should be kept constantly in mind when such articles are being considered as foods. While ordinary home-made beef tea, and all the extracts are next to nothing as nutrients, they certainly have a place as stimulants, and as flavorings for other more nourishing foods, not so pleasant to the palate.

There are in the market preparations of blood and whiskey, under various trade marks, which have a large sale, I presume, and which are highly praised by some, who, I am afraid, do not always take into account their composition, and while these have a place in our armamentarium, we should not lose sight of the fact that they contain an alcholic stimulant and are very offensive to the special senses of smell and taste, and their food value is not very great.

The juice of meat which has been heated sufficiently to swell and dissolve the envelope of the muscular tissue, can be easily expressed by an ordinary lemon squeezer, is agreeable to the taste, possesses a food value of about seven per cent., and answers an excellent purpose to help bridge over, or it may be used as a vehicle for peptones, (when these are offensive to the taste) or for uncooked eggs, when it is desired to increase the quantity of food, and beef juice is agreeable to the palate.

John Wyeth & Brothers made a delicious beef juice, agreeable to the most fastidious, which can be found at any druggist's, and for this reason is most readily obtained, having a food value of three per cent., which is a great convenience.

When heated in the test-tube Wyeth's

beef-juice becomes solid, thus showing the percentage of soluble coagulable albumen. It also contains the hæmoglobin of the meat unaltered.

Of course these meat juices should not be heated above 110° F., if we care to retain the "juice" properties, although when coagulated it will make an excellent beef tea. This beef juice answers the purpose of a vehicle for any of the more nutritious food stuffs, and it may be diluted with any of the carbonated waters. As a stimulant, Wyeth's has no superior, embodying in a concentrated form all the albuminoids of beef. It is perfectly stable in every climate, contains no alcohol or other preservative, excepting common salt.

I am in the habit of prescribing this stimulant in preference to alcohol under many circumstances, thus saving the depressing reaction.

It will be found of service in acute gastritis, when no other agent will be tolerated by the stomach. It can readily be demonstrated by heating a one-third solution in a test tube that albuminoids are present as stated.

Combined with grape juice we can easily administer enemata in typhoid and other grave conditions, when loathing for good food would make the case almost hopeless otherwise, and thus supporting our patients over a trying moment, we hope for much more than could be reasonably expected under other circumstances, and death by exhaustion from neglected nutrition will be avoided.

A simple and inexpensive extract of beef which can be made at home has been recently suggested by Dr. Jacob Price, of Westchester, Pa.

℞ Hydrochloric acid officinal.....f 3 i
Essence of pepsin (Fairchild's).....f 3 ii

Of this mixture three teaspoonfuls are to be added to one pound of finely minced lean beef, and placed in a quart jar in a cool place which is to be nearly filled with *cold* water, tightly covered and well shaken every half hour for two hours, when it will be ready for use. It may be salted and flavored at pleasure. When the question of expense is to be considered, this will be found to answer the purpose excellently.

The details must be carefully carried out in preparation.

The last candidate for our service in the way of a predigested food, from our friends, the Fairchild Brothers, has been named "Panopepton" and consists of bread and beef, with sherry wine as a preservative. We are assured by this reliable house that only prime beef and the best wheat flour are used, and that both are thoroughly cooked, properly digested, concentrated in vacuo, and contain all the elements requisite for the nutrition of the body.

Where a stimulating and nutritious reconstructive is required at the same time, Panopepton will be found much more useful and agreeable than the blood and whiskey abominations.

When one has been chilled, there is no agent which so promptly and effectually warms up the body as a cup ot hot sarcopeptone, and it is far better than any alcoholic stimulant.

Pneumonia patients will do much better, when they are able to tolerate hot sarcopeptone every two hours from the beginning. The course will be more rapid, the crisis will be passed with safety, and rapid convalescence result.

We may emphasize this mode of treatment in our diphtheria patients.

The entire absence of proteids is a marked feature of bile, and the bile has no digestive action upon proteids whatever. Foster says that "we may fairly assume that the secretion of even such a complex fluid as the bile, is in the main, the result of the direct metabolic activity of the protoplasm of the hepatic cells."

It is enough for our present consideration that tissue waste and albuminoid excess are burnt up (mainly in the liver), and oxidized in a descending series of retrograde albuminoid metamorphosis.

There is certainly an art in preparing and serving articles of food, and it may be made of great utility, especially with the acutely ill. Not that it should be used to seduce the patient to take food which will not be tolerated by the stomach, but rather that the sight of it, because of its dainty neatness and surroundings, will stimulate the special senses in such a way to excite the appetite to as nearly the normal point as possible. To many, the æsthetic element, which adds attractiveness, will increase the digestibility of the article ingested. Upon the cook and the nurse the physician is dependent for much

that will help in the convalescence of the patient.

Acute disease is always accompanied by fever, consequently the physician should carefully weigh the effects of the different classes of foods in kind, in quality and in quantity, in order to successfully overcome the loss of body weight, and to offset the increase of urea and the excessive excretion of carbonic acid and water, in order to avoid the danger limit. I cannot urge too highly the use of carbonated waters in these cases; and they are to be used freely, all that can be borne, as they will be most agreeable to the patient in quenching thirst, they are refreshing, reduce abnormal temperature, and digestion and assimilation is better performed in their presence.

It is worse than useless to give a patient food he cannot digest in any form or quantity, and we cannot be too careful in this regard during convalesence.

It is just as important to watch the excreta as it is to know what goes into the stomach as food.

There is no point in typhoid fever which is of more importance than the quality and preparation of the food, carelessness or over zeal in this regard resulting in fatal results.

Diphtheria is one of the acute affections in which the pushing of nourishment to the utmost demands the constant attention of the physician himself, for it is not safe to trust so important a matter to any attendant, and the patient who cannot be induced to take sufficient food is going to die!

The buccal cavity can be kept clean and in condition to tolerate food, with a solution of Sanitas fluid; and this is important, because patients will refuse food oftentimes because of the sensitive or foul condition of the mouth.

The palate and individual idiosyncrasy are important factors in feeding the sick, and in choosing variety the palate as well as the question of nourishment should engage our attention.

It has been well said by another that "when life seems passing away under their eyes, the friends will often shrink from tormenting, as it seems to them, the sick man with food. Let them not despair; many a one has recovered after the doctor has taken his leave with a sad shake of the head, and without making a fresh appointment. And let them also be stimulated by the fact—namely, that the pains of death are aggravated, if not mainly caused, by the failure of the nutrition. Even when apparently insensible, the dying suffer much increased distress from want of food, though they cannot express their suffering."—*N. Y. Med. Times.*

SOCIETY REPORTS.

CINCINNATI OBSTETRICAL SOCIETY.

[OFFICIAL REPORT.]

June 28, 1894.

CLINICAL REPORT OF FOUR CASES OF APPENDICITIS; OPERATION AND RECOVERY.

DR. RUFUS B. HALL: I present this short report to-night as illustrating the different conditions for which we are called upon to make operations for the relief of this disease.

CASE I.—R. D. H., a physician, living in North Liberty, O., consulted me February 9, 1892. At that time he was unable to walk from the effects of his illness, having been confined to his bed for several weeks. His weight, which was usually 200 pounds, had fallen to 140 pounds. He was just recovering from his fifth attack of appendicitis within eight months, each confining him to his bed for from a few days to two or three weeks. He had the usual symptoms of appendicitis; a well-marked induration in the region of the appendix, with tenderness and pain upon pressure, which had never entirely disap-

peared after the first attack, in June, 1891. He had been able to practice medicine between the attacks, but always with some discomfort in that region. During these attacks he suffered greatly from irritability of the stomach and nausea. This was so marked he was unable to take any except liquid food, and that in small quantities. For three weeks his stomach was unable to retain more than an ounce of the blandest nourishment at a time. His food was practically limited to milk and lime water. During his last attack he suffered greatly, requiring morphine for the relief of the pain. He was brought to the city and entered my private hospital at that time, being unable to straighten his right leg on account of the pain it caused in his abdomen. His temperature was normal, his pulse 112.

After a thorough examination, operation was advised and made February 12. Upon opening the abdomen the adhesions were found to be extensive and very firm, and it was with considerable difficulty the appendix was found. There was no pus present, but the appendix contained five foreign bodies, about the size and appearance of grape seeds. After careful examination these were determined to be concretions. He made a prompt and complete recovery, returning home March 18. Within three months he weighed 200 pounds. He has no return of his former trouble, and is now actively engaged in the practice of medicine in a country district.

CASE II.—Miss E. S., Columbus, O. Occupation, stenographer; aged twenty-six. She had always enjoyed good health previous to the present illness, which came on in the night of December 24, 1893. On the morning of that day she left Columbus to travel to Cleveland and spend the Christmas holidays with a sister in that place. She attributed her attack to the ride on the cars, but as to the truth of that I have serious doubt. Within a few hours after the pain commenced it became so severe that a physician was called; he at once diagnosed appendicitis. She was very ill for three days, but on the fourth day the symptoms abated, and he advised her removal home. This was done, and for three or four days she improved, but on January 1 her temperature again rose to 103° and on the next day to 104°. On the night of January 4 I saw the patient at her home. Her pulse was 130, temperature varying from 102° to 104°, and a well-marked induration in the right iliac fossa, with occasional vomiting.

Immediate operation was advised, assented to, and made the following morning.

Upon opening the abdomen, extensive adhesions were found adhering to the anterior abdominal wall. These were carefully separated towards the brim of the pelvis until we opened into a cavity containing several ounces of chocolate-colored bad-smelling pus. As is my custom in cases where suppuration is great, no extensive search was made for the appendix. The parts were carefully cleansed and drained. Upon the fourth or fifth day the pus contained a slight quantity of feces, and this objectional material was present for the following ten days. At the end of four weeks there was no indication of intestinal leakage, but it was five weeks later before the wound was entirely healed. She made a complete recovery, and is now back in the office in perfect health.

CASE III.—E. M., aged twenty-six, farm hand, Mason, O. I saw him in consultation, April 12, 1894, when the following history was elicited. The patient was taken suddenly ill about ten days before my visit with pain in the right side of the abdomen, which soon diffused itself over the entire abdomen. He had a temperature ranging from 101° to 104° from the first. The first few days of his illness the physicians gave him physic and thoroughly emptied the intestinal tract; after that time he was given milk and broths, but no physic. He had occasional doses of morphine, but gradually grew worse. Upon examination I found that the colon was largely distended with feces, which consisted of scybala following the use of milk diet, and the intestines were greatly distended with gas. In the right side of the abdomen the tenderness was well marked. He had been given chills and sweats for two or three days, with every indication of suppuration. An operation was advised as soon as the bowels could be emptied of their contents, which in this condition is not easily to accomplish. After repeated doses of salines and many enemas the bowels were thoroughly emptied, and in response to a telegram I went to Mason on

the morning of April 14 and made the operation.

In separating the firm adhesions to the anterior abdominal wall, we opened up the abscess cavity, holding several ounces of dark-brown, offensive pus, having a distinctly feculent odor. This was thoroughly cleansed and drained. At the upper end of the incision we had opened freely into the peritoneal cavity. This was closed off with gauze packing and the wound dressed, practically as an open wound. The patient had a fecal fistula for about three weeks; at the end of six weeks the wound was perfectly closed. He is now doing his usual work as a farm hand, and enjoys good health.

CASE IV.—W. W. P., aged forty-one, physician, Fredericktown, Ohio. He had his first attack of appendicitis about six years ago, at which time he was confined to the bed for a few days, the soreness remaining a week or two. After this time he had no tenderness or pain in this region until September, 1893, when he had another well-marked attack of appendicitis, confining him to bed for several days, the soreness and induration not disappearing for about three weeks. After this he resumed work until December, when he had a third attack of about the same duration. In January, 1894, he had a fourth attack about like the others, but in March he had a very severe one, confining him to bed for a week or more, the pain and induration not disappearing for about six weeks. On May 10 he had the sixth and last attack. He was unable to work after that time. He consulted me on June 5, at which time he had a well-marked induration the size of a small orange in the region of the appendix, which was exceedingly sensitive to pressure. He was able to walk, but not with any degree of comfort, and had come to the city to have the operation made. The temperature was above normal after the last attack. For three months he had practically lived on liquid food. His weight had decreased from 160 to 140 pounds.

The operation was made at my private hospital, June 7. Upon opening the abdomen and separating the adhesions, which were firm, we opened into a pus cavity holding about half an ounce of pus. The appendix was crescent-shaped, and in the hollow of this crescent, between the coils of the intestines, was the pus cavity. The appendix was about the size of the little finger, except for about one-third of an inch just where it joins the colon. This was about a quarter of an inch thick, and appeared cartilaginous. It was ligated close to the colon and removed. The distended portion of the appendix contained a small quantity of pus—perhaps a half-drachm. There were no perforations of the appendix that could be determined. This patient has made an easy and prompt recovery, without an unfavorable symptom.

This patient had consulted many physicians and received as many opinions, which, I am sorry to say, differed very widely. Even at the last of his illness, the men who do not practice surgery advised delay, but the men who do practice surgery advised operation. This should not be. I think it is time for the profession to get together in their opinion in cases of appendicitis requiring operation. There need be no doubt about the advisability of operation in recurrent attacks of appendicitis, especially where they recur with frequency and severity, as they did in the first and last case. Again, there need be no doubt, even if it is the first attack, as in the second and third cases, where the temperature and other symptoms plainly indicate the presence of pus.

DISCUSSION.

DR. CHARLES BONIFIELD: I had a case of appendicitis last winter that I had intended to report systematically at some time, but the last remark of Dr. Hall causes me to report it now. The patient was a boy ten years old, whom I was called to see Christmas morning. He went from bad to worse, and in twelve hours had a general peritonitis; pulse about 130, and could not retain nourishment or food of any sort. Dr. Forchheimer was called in consultation. We discussed the advisability of operation, but neither of us were very much in favor of it; I, in particular, was not. At any rate, it was postponed until the next day, when we got his bowels to move. He then began to retain nourishment, and in about four days he was convalescent, and in a week I did not think it necessary to see him for a few days. When I came back I found a temperature of 101°, and this continued about a week. I made an examination for pus, but I was unable to feel anything through the abdomen or the rectum, and with nothing

but the high temperature to indicate it I did not feel justified to make an operation. There was some pain over the liver, but not very marked. About twelve days later his temperature ran up suddenly to 104°; I was telephoned for, and just as I got to the house they told me he had a very severe spell of coughing. I went up to his room, and found he had been discharging pus through the lungs. His temperature then fell, and in a week it was normal. In the face of the acute general peritonitis I do not think operation would have been justifiable. After the temperature continued high I would not have explored the liver, and think probably the abscess was above the liver. The liver was not specially enlarged at any time. Opening the abdominal cavity would simply have made it worse.

DR. HALL: What was the diagnosis of the first attack?

DR. BONIFIELD: Appendicitis.

Q. Could you outline a tumor?

A. The colon seemed to be filled with feces; you could map out an area of dulness.

Q. Your diagnosis was correct, I presume; what was the action of the abscess?

A. Acute general peritonitis.

Q. Septic in character?

A. I do not think it could be called a metastatic abscess.

DR. C. D. PALMER: His marked improvement was after the discharge of a quantity of matter?

DR. BONIFIELD: Yes, sir.

DR. A. W. JOHNSTONE: This is very interesting, and the one point I am glad to hear brought out and special stress laid on is not to operate while the intestinal canal is stretched to its full extent. I do not think any man is justified in making a laparotomy under those circumstances. One case of appendicitis, which some of the gentlemen present saw with me, turned out to be just a common colic caused by the fellow eating apples. No appendix was found, but the man got perfectly strong and well. I believe sometimes the appendix may slough out through the bowel and a chronic peritonitis left, which may be cured by an exploratory incision. In this case no appendix could be found. The colon was laid open from the ileo-cecal valve to the head; there was a blotch of cicatrices everywhere, and we had to separate a number of them. After I had gotten back it seemed as if we were going into the normal parts, and I stopped. There seemed to be some accretion, but this I found to be only the contents of the bowel. I took the drainage-tube out about the second or third day, and the serum poured for about a week. He came back in a few weeks and I did not know him; he said he had earned the money in a brick-yard to pay for the operation.

My first operations in this line were upon negroes down South. They were close together, and are living to-day.

I have seen men who no doubt had one attack of appendicitis; everything was asked to make the diagnosis perfect, and they are well to-day; so I am not prepared to go to the same extent the New York Academy does. But the second attack always calls for operation. It is then time for us to go to work. If the first attack is mild, I think it is safe enough without operation. I had an experience with a little girl, aged thirteen, who had menstruated her second time and completed it one Wednesday. The following Sunday she had jumped the rope, and had some pain, but did not call the doctor until the following Wednesday. I saw her about 1 o'clock and ordered her to the hospital. I found she was in shock, the temperature below normal (about 98°), and I ordered a cathartic. The next morning the temperature had risen a little, and I saw the child was going to die unless something was done. I made the effort, simply going through the abdominal wall, and I found a lot of feces, enteroliths, etc., and she died that afternoon. In these cases the gas must be removed before the patient is safe, and the whole question simply resolves itself into whether it is easier to do this before than afterward. I do not think it is safe to cut into the abdomen in any case before this is done, except in cases of stab wound. In the first laparotomy of my old assistant, down at Danville, the case was caused by the blow of an ax handle. In that case the bowels continued distended, and it was perfectly apparent that unless something was done the child would die. I assisted him in opening the abdomen, and we found nothing but a dry peritonitis and an enormously distended canal. When the intestines were gotten out we could not return them without opening them, and so we made an eighth of an inch

opening in the intestinal canal and let out all the gas and feces we could possibly get out that way. He made a beautiful recovery, which I think was due to the drainage. The introduction to the drainage-tube started the serum to flowing, and it just poured for several days. In proportion to the pouring of serum was the improvement of the child. Of course the difficulties of the peritonitis we know. We often find these cases with adhesions.

I do not think the appendix is put there for nothing, but that it is after all only a hollow lymphatic gland; it is simply a continuous Peyer's patch, and the volume of the serum I think is increased. It is there, and I do not think we have a right to take it out every time we find it. In the last year I have had the appendix in my hand three times, and several times have had to ligate the adhesions and take them away. Now, when the appendix is perfectly normal, except from inflammatory bands which have come from the tubes and ovaries, I cannot understand why we should consider it necessary to remove it. I saw a normal appendix exhibited in the New York Academy, taken out just because the gentleman had his hand on it. I do not think we should hunt for the appendix in cases of abscess. In the case I had within the last week or ten days, a large abscess of the ovary had been discharging through the alimentary canal. It had continued a year or two. I got the ovary out, but could not get the tube out without wounding the intestines. I expected to curette the case afterward. I found the sinus had gone down to the broad ligament, and then out into the intestine. It has made an uninterrupted recovery. I think when we find the thing we are after to save the life of a patient we ought to quit, and that is a law we ought to follow more closely. My old professor used to say: "Boys, don't muss and muddle; don't go too far, because every time you touch an intestine or break an adhesion you add that much to the risk, and the thing to do is to do as easily and smoothly as possible the one thing you go after, and leave the rest alone."

DR. W. H. WENNING: I have not had any personal experience, and come just to learn; but one remark of the last speaker brought a query to my mind—whether in some cases with accretion, instead of removing the appendix, would it not be possible by pressure to force the substance into the main gut, and leave the appendix alone? I have not my mind definitely made up as to the proper treatment of these cases. Certainly the medical aspect has something in its favor. I am sure many cases are cured by medical treatment and before we determine what is the proper line of treatment we ought to listen to the medical side. I would like to hear Dr. Cleveland's views on this question.

DR. J. L. CLEVELAND: My opinion, based on my own limited observation, is that the majority of the cases of appendicitis get well. I think very likely every practitioner has a number of cases of appendicitis, and it is only now and then that we find it necessary to call in assistance to operate for us. In fact, in twenty-five years I have never had a case that was operated upon. In one case it would have been very fortunate had I called in a surgeon, but in that case I did not fully realize what I had to deal with until it was too late. I can recall some three or four cases that have entirely recovered without operation. The statement has been made by experienced men, and I do not doubt it, that when the appendicitis appears more than once it is probably well to operate. While I am not in a position to contradict that, still I am of the opinion that frequently even these cases get well without operation. One case especially, which I have in mind, a man probably thirty-five years of age, has had some three or four distinct attacks of appendicitis. At one time I advised an operation, but after a series of weeks he recovered. He simply had an acute attack of pain, a localized peritonitis around the region of the appendix, and it lasted three or four weeks. It was not like the fever we have when pus is present, and if there was any pus I did not discover it. He is now perfectly well and is doing his work. I had another case, which occurred in a woman, showing that these cases may be cured sometimes by simple puncture. She had one or two attacks of appendicitis, and I wanted her to be operated upon—insisted upon it, in fact—because I thought otherwise she would die. After two or three weeks, the peritonitis not becoming general, I could feel a fluctuating tumor, and I was so well

satisfied that I had felt justfied in sticking a knife into it without saying anything to her about it. Afterward I increased the opening and washed it out. I mention this case to illustrate an experience which I expect others have had, namely, that the appendicitis has softened in some cases so they have thought best to stick a knife into it. I have had another case when resulted the same way. Our judgment in these operations is to a large extent influenced by what we see. The general practitioner only sees the cases which come under his own observation, while the specialist sees not only his own but also the cases coming under the care of others. I feel satisfied, from want I read regarding the operations in the East, that they are certainly carrying things too far and operating too freely; notwithstanding these patients usually recover, I do not think it is an easy operation by any means. The point I would make is that the majority of cases of appendicitis get well under the medical treatment and only the serious or worst cases come under the observation of the laparotomists.

Dr. Johnstone: I remember, while practicing in Kentucky, I went down in the mountains, in that ignorant Egyptian land, and I found a patient who was not only pregnant but had a large lump in the groin. They would not let me touch it, and I returned home. The doctor wrote me in three or four months the result. She got well, but with the thigh drawn up. She would not let him touch it, and it dissected away up the side and down the thigh, and it discharged about two gallons of pus. At the time of her confinement the leg was drawn up in such a position that it was difficult to get the child out. This illustrates how nature will sometimes bring these patients through, but with what deformity! When cases have the second and third attacks of appendicitis, the percentage of recovery is very greatly reduced. But when we find it is safer to operate than to let the patient alone, I think a man is a simpleton not to go ahead and operate.

Dr. Hall (closing): Certainly no man would take off an appendix which was healthy, unless he resided in New York. I have frequently pulled them off from adherent pus-tubes or suppurating ovaries, and pushed them out of the road. I simply pulled them off as I would an adhesiou with any other organ—as a coil of the intestine for instance—and let it be. I removed one appendix, however, that was fairly healthy, except it was adherent to a large fibroid tumor. I have reported this before. I did not recognize it as the appendix, but mistook it for a vessel. I put it in a clamp, because the blood from it squirted over my head. The patient recovered. That is the only time I have ever been guilty of removing a healthy appendix. I think the suggestion by one of the speakers, of pushing the accretions back into the gut, is a very problematic one. In fact, in all these cases that we are called upon to operate there is an inflammation rapidly going on, and the narrowest calibre is to be found where the appendix joins the gut. In the first case reported the physician had several foreign bodies in the appendix. There was a sort of cartilaginous portion near the intestine, through which there could be found no hole whatever, and I think it would have been perfectly safe to have cut it off without any ligature. I will grant, if such a thing could be done, it would be perfectly safe to do so, but I think we would very rarely find a suitable case. I have never considered the question to any great extent, but it has never occurred to me that that would be a good way to treat these cases.

In reference to the medical treatment, I think we all agree with Dr. Cleveland, but I think we should get together, and medical men should refer the cases for operation before they reach the autopsy-table. After they have had a second or third attack, especially if those attacks occur at short intervals and are severe, there should be no question about operation. I believe they should all be operated upon. I have the record of a case, however, which has recovered now five or six years after the ninth attack in two or three years. The patient learned to lead an invalid life, because exercise would bring on the disease, and nature cured the case without operation. I have the complete records of one case that had seven or eight exceedingly mild attacks and then had an exceedingly severe attack and went to the graveyard. When I saw her it was impossible to count the pulse, and she died in an hour or two afterward. I have not reported these cases for a purpose of drawing a line between those cases which should be operated upon, for I consider that each

case is a law unto itself, and the party having the patient in charge must be the judge.

DR. CLEVELAND: How young a child can have appendicitis?

DR. HALL: I have operated upon one nineteen months old.

ELECTRICITY FOR STERILITY.

DR. C. D. PALMER: It will be remembered that several months since I made mention of a case of sterility, which I considered cured by means of the galvanic current. It was a form of sterility which is perhaps one of the most, if not the most, common form. It is a congenital condition, arising in the second period of development of the uterus, in which the cervix becomes elongated, the os externum very small—pin-holed, and the whole uterus is more or less imperfectly developed—the infantile uterus.

The galvanic current was used as follows: The positive pole externally over the abdomen, and the negative pole placed intra-uterine, so that the cervical canal might be dilated, and the whole uterus enlarged. After repeated applications, and occasional intermissions of any treatment, the patient became pregnant. When I had reported the case to this society she was in the seventh month of utero-gestation. She underwent parturition a few weeks since. Toward the end of the normal term of gestation I visited her once a week, to see what progress was being made in the natural process of obliteration of the cervix, occuring usually within the last two weeks. Now, noticing that the os externum was still small and contracted, although she had approached to the time of parturition, according to the Naegeli rule, I commenced an artificial dilatation with my metallic forceps, using first the smaller and then the larger size. This procedure induced feeble pains, and in a few days genuine labor set in. But the first stage was the most prolonged and perplexing one I have ever witnessed, extending over a period of three days before a sufficient amount of dilatation had been accomplished to introduce my hand within the uterine cavity. By this time the patient was very much tired out, had a frequent pulse and slight elevation of temperature. The examination revealed a right sacro-anterior position of a breech presentation, a complete extension of the fetal legs on the flexed thighs, and a contracted pelvis of the mother in its antero-posterior diameter of the brim. This pelvic contraction did, and could have no influence in delaying the progress of the first stage of labor. The same was due only to the imperfectly acting uterus. Needing assistance, I sent for Dr. Edward Mitchell, and after a hot-water antiseptic vaginal injection, and the administration of chloroform to complete anesthesia, I commenced podalic version. The high position of the fetal feet within the uterus, and the somewhat tetanic condition of the uterine walls, delayed me in bringing down both feet and the delivery of the whole body of the fetus, save the head. Anticipating that I might have to contend with a retained head because of the maternal pelvic contraction, after a reasonable traction on the fetal neck, favoring utmost head flexion, I applied my obstetric forceps, and made a prolonged vigorous traction. Then I requested Dr. Mitchell to continue this forcep traction, while with the two fingers of the right hand I pushed back on the occiput, and with the same fingers of the left hand hooked in its mouth I pulled down the lower jaw. These combined efforts of both were successful in effecting delivery of an asphyxiated child. Dr. Mitchell then devoted his entire attention to the resuscitation of the child, and he was successful after prolonged efforts. Of course, the delay in the delivery of the child's head and pressure on the umbilical cord explained this asphyxia.

Prior to the commencement of labor pains, and before artificial dilatation of the cervical canal, I measured the exterior of the pelvis in three of its diameters, to detect, if possible, any malformation. External pelvimetry revealed none. This procedure only proves how unreliable external pelvimetry is in confirming a pelvic contraction. Many pelvic deformities, if slight, especially the juxto-minor can be detected only in parturition itself.

After the delivery of the placenta, as is my invariable custom, I proceeded to irrigate the vagina with hot water, antiseptepticized with bichloride (1:4000), and then observed an unusual post-partum flow, although the uterus itself was in normal position and size. The blood

seemed to proceed from the vagina, and it could be seen coming from a rupture of the veins of the "bulb of the vestibule." The latter was checked by a ligature passed beneath the bleeding vessels, and suspecting a rent of the cervix as the cause of the former, I exposed the cervix with a large Sims' speculum, and passed three silk sutures to close this rent. The patient made a smooth and uninterrupted recovery, notwithstanding she was nearly pulseless after the sutures were placed.

Among other questions which may arise in discussing this case, I wish to state that it has been my habit to stitch a lacerated cervix immediately after parturition, if the tear is noticed as much as to within the vaginal vault, and always, if the torn cervix walls are the source of the post-partum hemorrhage. There is but little doubt that some of the few cases of post-partum hemorrhage, occurring at the present time, and ending fatally, might be reversed by inspecting and suturing primarily the rent structures.

Some may think that the method of effecting dilatation of the imperfectly dilated cervix, by incisions, as recently recommended, might have been practiced in this case. While the cervix was imperfectly dilated for a full passage of the fetal head, still it was dilatable. The delay in the fetal head delivery was from the contracted pelvis of the mother. It has always seemed to me that this obstetric surgical procedure of incisions of the cervix is adapted for cases only in which the imperfect dilatation is owing to morbid organic changes within the structure of the cervical lips, and not to cases of imperfect dilatation from functional causes. While dilatation was about three-fourths complete when podalic version was performed, the cervix was soft and dilatable. This, then, is not a condition calling for cervical incisions.

DISCUSSION.

DR. E. W. MITCHELL: I had the pleasure of seeing this case with Dr. Palmer, as he has stated, and I can certainly congratulate the doctor on the result, both to the mother and to the child. I expected the child would be asphyxiated beyond recovery, and I certainly think the doctor has every reason to be congratulated upon the skill he showed in the management of the case, which was unusally perplexing from the beginning to the end.

These cases of infantile cervix are always troublesome. They are slow in dilating, and they are far more liable to occur in women who are delicate and have not very great muscular strength; the woman becomes exhausted and worn out, and they are almost certain to be lacerated, no matter in what way the delivery occurs. The question might arise whether the use of electricity in this case might not have altered the normal tissues so as to predispose to the rigidity and the liability to laceration. From the fact that a cervix like this will almost always be lacerated any way, I think it is doubtful whether the electricity has any such effect. When I saw the case there was in my mind no question whatever but we had come to the right conclusion, that the time had arrived when the woman should be delivered. The cervix was sufficiently dilated and sufficiently dilatable for the dilatation to be completed by podalic version.

As to whether the cervix should be immediately repaired: After we had repaired the perineum and placed a suture in the bulbo vestibule, the hemorrhage at first seemed to have ceased, but when we found it was coming from the lacerated cervix. I have never made a practice of the immediate repair of the cervix. It is an operation that is not so difficult to do at this time, and yet then your patient is exhausted and the friends are anxious that she shall rest, it takes a certain amount of tact to get the consent of the patient and friends to proceed with the repair of the cervix as well as some courage on the part of the operator to go ahead with it. I think the best practice, probably, would be to repair it immediately, and I am not sure but I shall come to that practice.

In this case the doctor tells me the repair of the cervix was very good after the stitching. The case illustrates the value of the speculum in cases of deformity.

DR. C. E. CALDWELL: The case which I wish to report was seen by Dr. Porter with me nearly two years ago.

I was called to deliver a dwarf, forty-one years of age, and a primapara. I found the pelvis small, but there seemed to be no irregular contracture. I did not use a pelvimeter, but I made up my mind that a fair-sized fetal head could be deliv-

ered. I was called to see her in the night. I came to the conclusion that the head would not be discharged spontaneously, and I called Dr. Porter, who administered chloroform while I proceeded to apply the forceps. When I tried to apply them it seemed they were almost wedged between the head and the pelvic bones. They were finally adjusted, and the head with great difficulty delivered, after which the child was quickly delivered. There was a laceration of the perineum laterally, which also ran up quite a distance. The cervix was torn, and there seemed to be nothing to do but to repair everything. I think about fifteen stitches were introduced. The patient recovered uninterruptedly, and in three weeks was doing her own work. She has since been in perfect health.

I am persuaded, where there is a laceration and a large surface for absorption, the only thing to do is to primarily unite the cervical wound. Of course this is to be done only when the patient is able to stand it, but even when considerably exhausted the few extra minutes spent in a repair of the cervix is to the advantage of the woman rather than to her disadvantage. It seems to me there will then be no necessity for a second trachelorrhaphy.

Dr. Wenning: Whatever I have to say will not be said in criticism of Dr. Palmer's case. It is always easier to tell afterward what could best be done. It seems to me, considering the length of the first stage, that this was a typical case for deep incisions of the cervix, and it is in just such cases that they are recommended. Possibly, if that had been done earlier, the labor would have terminated sooner with less difficulty. This, of course, is an intentional traumatism, and we cannot tell how far the laceration would have extended beyond the cut surface. Nevertheless, if we can carry the incision just to the proper degree, so we can introduce the hand or instrument, I think it would likely obviate the necessity of a laceration, which would otherwise inevitably occur. Therefore, why not make an incision sufficient to introduce the hand and deliver? This, of course, brings us to the question of suturing. In every case the cervix should be sutured, just as any other wound. I think in the great majority of cases it is not necessary. The primipara always have a laceration of the cervix, just as well as of the fourchutte, but if it does not extend very far up the hemorrhage will not amount to much. If there is a spurting of a ruptured vessel it should be sutured. The deep incisions are necessary sometimes for a double purpose: First, to prevent further hemorrhage; second, to insure against infection.

Dr. Bodifield: It seems to me there is one other question that might be brought up, and that is whether it is worth our while to try to cure sterility in cases of infantile cervix.

I have never been in the habit of suturing the cervix unless there is considerable hemorrhage. I think frequently there will be good union, and not enough scar to amount to anything. I have always had some hesitation about making what seems to the bystander such a formidable operation. Of course, if the hemorrhage is sufficient to be alarming, it should be stopped as well as if it were from any other part.

Treatment of Cerebro-Spinal Meningitis by Hot Baths.

Dr. Aufrecht (*La Semaine Médicale*, No. 48, 1894) in a case of seemingly desperate cerebro-spinal meningitis obtained remarkable results with very warm baths. The case in question was that of a workman of twenty-six years, at the third week of the disease. For ten days he had been comatose with subnormal temperature (36° C.), and a rapid and small pulse. Subcutaneous injections of camphor and the internal use of the iodide of potash led to no results, while his condition continued to grow worse steadily. On account of the cold and collapsed condition of the patient Aufrecht tried very warm baths. After the first ten baths at a temperature of 40° C., and of ten minutes duration, he remarked a notable amelioration. The patient came to himself little by little, the stiffness of the nuchal muscles and the strabismus decreased more and more, and after twelve baths, all the morbid symptoms disappeared completely and definitively.—Translated for The Medical and Surgical Reporter by the Translator, F. H. Pritchard, A. M., M. D.

CURRENT LITERATURE REVIEWED.

IN CHARGE OF ELLISTON J. MORRIS, M. D., AND SAMUEL M. WILSON, M. D.

NEW ORLEANS MEDICAL AND SURGICAL JOURNAL

for July. Dr. A. J. Bloch gives some of his experience with cases of

Sexual Perversion in Females.

He divides his subject under three heads of the Krafft-Ebing classification. "Paradoxia-sexual excitement occurring independently of the period of physiological processes in the sexual organs." "Hyperæsthesia—Increased desire." "Paræsthesia—Perversion of the sexual instinct—excitement from inadequate stimuli."

Cases are described under these heads:—a girl of 14 complaining of nervousness and pallor, and failing to improve under tonics and exercise, was examined carefully and the clitoris being found bound down by its prepuce was liberated, and the girl stopping masturbation, which she had practiced, improved in health.

The second case was a girl of 2½ years, whose mother is a victim of the habit, and with other neurotic antecedents. In this case liberation of adhesions was insufficient, and the clitoris was removed as completely as possible, almost at the pubic attachments.

Another case, classified as hyperæsthesia resulting from paradoxia, was a young girl complaining of retention of urine. The complaint was without foundation, but each catherization cau ed an orgasm.

Another case was a married woman, a masturbator, who found no enjoyment in natural intercourse, The removal of cystic ovaries led to a great improvement in general health and ended in a cure.

Still another case was a woman complaining of a swelling in the mammary gland. The gentlest manipulation led to an orgasm, and the swelling proved to be purposely produced.

Dr. E. D. Martin reports a case of

Simple Hypertrophy of the Mammary Glands.

The patient was an anæmic, though well-grown colored girl of 14 years. The breasts were about thirty-seven inches in circumference, and weighed about ten pounds each, and though causing lancinating pains were complained of mainly on account of their size and weight. Large doses of iodide were ineffectually given for a while, after which the glands were excised separately and the patient improved greatly in general health. The glands were edeno fibromata. The case is reported to show the uselessness of iodide in humors of this size, and the author thinks it ineffectual, even in small humors, if they are not syphlitic.

Other papers in this issue are on "Diagnosis of Hepatic Colic," by Dr. E. M. Deparquier; "Two Cases of Suppurative Endometritis," by Dr. P. Michinard; also reports of the proceedings of the Clinical Society of Maryland, Morehouse Medical Society, Louisiana State Medical Society, and Orleans Parish Medical Society.

PERISCOPE.

IN CHARGE OF WM. E. PARKE, A.M., M. D.

MEDICINE.

Chlorine Water in Diphtheria.

Dr. Schubert reports on the value of chlorine water in diphtheria. After an experience of many years he is most enthusiastic on the subject, claiming that no known treatment equals that of internal administration of chlorine water.

He gives a teaspoonful of a mixture consisting of two parts of chlorine water, and one part of distilled water, repeating every two or three hours according to the gravity of the attack. On account of the pungent odor the nose may be held for smaller children. Gargling or painting the throat is superfluous, but no water should be given after the draught. As a prophylactic the foregoing mixture may be given two or three times daily.—*Dental Med. Wochen.*

Croup.

To summarize briefly the medical treatment of croup that will give the little victim the best chance of recovery is as follows: A warm room, the air of which is to be saturated with moisture; an emetic of turpeth minerol *to be repeated whenever the respiration becomes embarrassed;* if the bowels are constipated, a sufficient amount of mild chloride of mercury to move them thoroughly; ice to the throat, either in a rubber bag or bladder; if thirst exists, pellets of ice internally; quinine *to decided cinchonism, which is to be maintained;* a sufficient amount of hydrate of chloral to allay spasms of the air passages, with decided doses of belladonna; the inhalation of steam, medicated or not as may suit the peculiar belief of the individual practitioner; the juice of the pineapple, trypsin with carbonate of soda in warm water; to be supplemented by the administration of a suitable amount of easily digested food.—*Medical Brief.*

SURGERY.

Morton's Disease.

Bosc (*Arch. Gen. de Med.*, July, 1894), begins a study of this metatarsal neuralgia. It is limited to the anterior part of the foot, and to the metatarso-phalangeal joint, usually of the fourth toe. The disease consists in attacks of pain, generally localized to this joint, but at times radiating to adjacent parts. The attack begins suddenly, and the pain may be excruciating, the patient often feeling compelled to take off his boots. Walking is prevented, and the leg is flexed. The pain usually ceases rapidly on repose, but returns as soon as the foot is put to the ground again. The attacks have a variable duration from a few hours to a whole day. They may only recur at long intervals, but occasionally every two or three days The attacks need not be so severe as described above, the pain being more dull. In the less marked attacks the pain may only produce a slight giving of the leg. There may be vague pain during the intervals, and much cutaneous hyperæsthesia. At times the disease may really be termed chronic. The attacks of pain may react on the patient's nervous system; he may become depressed, and is haunted by fears of further attacks. There is absence of any local sign of disease. In the case related here by the author there was, however, some redness over the plantar surface of the metatarso-phalangeal joint, and pressure here produced the pain. There was also marked hyperæsthesia.—*Ibid.*

Railway Spine.

The great increase in railway travel has brought into prominence certain surgical injuries which assume great importance. These Dr. H. J. Saunders classifies, in the *Columbia Medical Journal*, into those in which some visible mischief is done, and those where no apparent harm has been sustained at the time of the accident. It is for the latter class of cases that railways are so often sued. The means of diagnosis are:

1. The absence of any apparent injury to the spine adequate to cause disorganization or derangement of the cord.
2. The time of development of the disability.
3. The nature of the symptoms.
4. The history of the patient, both personal and family.
5. Certain diagnostic symptoms to be discovered by careful examination of the organs of the body, such as changes in the fundus of the eye, the reaction of degeneration, lessened or exaggerated tendon reflexes, etc.

Too much care cannot be exercised in giving the prognosis in these cases.

A Disease-Proof Suit of Clothes.

A "disease-proof" suit of clothes, intended to be worn by an operating surgeon, has been patented at Washington. According to the description given to it, it is a complete suit of rubber armor, resembling the dress of an ordinary diver, and is constructed on air-tight principles, so that no disease germs can enter. There is a small pair of bellows beneath each foot, which, being compressed by the action of walking, blows fresh air in an ingenious manner through the armor. This air enters and is filtered through a germ-proof diaphragm under each of the feet, passing upward and out through another diaphragm arranged at the top of the head.—*Canadian Practitioner.*

OBSTETRICS.

Treatment of Early Abortion.

A conservative treatment of early abortion is recommended by Schauta, of Vienna, in a recent article. The old rule that pain and hemorrhage combined mean inevitable abortion he does not indorse, and thinks the accident preventable as long as the hemorrhage is not excessive or the cervix dilated He does not try to check the bleeding and trusts to rest, which is continued for eight days after the last bleeding. In those cases where the os dilates and abortion becomes inevitable he tampons with a strip of iodoform gauze, about two yards long and the width of three or four fingers breadth. He prefers to retract the perineum with the fingers of the other hand instead of using the speculum and renews the tampon at the end of twenty-four hours at the latest, removing it sooner if the appearance of sacral pains indicates that the ovum has been exposed from the womb. This method of treatment is in sharp contrast to the radical advice so often given of late to go in at once and curette out the womb as soon as an abortion becomes inevitable, a practice which Schauta objects to because of the danger of leaving fragments of membrane behind.— *Western Lancet.*

The Diagnosis of Extra-Uterine Pregnancy.

The following symptoms suggest ectopic pregnancy:

1. The absence of menstruation, or a flow coming at irregular intervals and of uncertain duration.
2. Pain of severe and spasmodic character, which may be permanent at first, then absent for some weeks, to return later with renewed vigor.
3. Vaginal discoloration — a symptom of some importance, yet often noticed in cases where some other form of pelvic tumor is present.
4. General signs of pregnancy, such as nausea, enlarged and tender breasts, increase in size of the papillæ, darkened aureolæ, milk in the breasts, ballottement, the presence of a tumor, irregular menstruation, and possibly gait.
5. The history of having had a child or miscarriage. This is important, as cases occurring in nulliparous women are rare.
5. Expulsion of decidua. This symptom is of great importance, although in the majority of cases we are not fortunate enough to have it present, or if present the clot and shreds of

tissue are thrown away before a microscopic examination can be made.

7. Increase in size of the uterus, with the fundus either pushed forward or to the right or left side.

8. Elongated, soft, and patulous cervix.

9. The appendages on one side containing a thin-walled and tender cyst. The fact, however, that a tumor is felt upon both sides should have no bearing upon the diagnosis, as one of the tumors may be due to extra-uterine pregnancy, and the other to some other form of tubal, ovarian or pelvic trouble.

10. Pulsation of vessels in neighborhood of cyst.

11. The rapid increase in the size of the tumor.

12. Presence of fœtal heart sounds.

13. Presence of placental bruit.

14. Feeling the small parts of the child, either through the vagina or rectum, or by combined manipulation.

With diagnosis made the author holds that the right policy is to operate.—G. H. Haven, in *Bost. Med. and Surg. Jour.*

Sore Nipples.

Dr. T. E. Teter, in *Omaha Clinic*, says: If the following sentence, "A sore nipple causes great pain when the child nurses," which occurs in a very valuable "System of Obstetrics," was reversed, it would approach my experience with this important disease. I have found great pain when the child nurses is generally followed by inflammation, excoriation, fissure and sometimes mastitis. The pain which is the first symptom of sore nipple is caused by sudden tension on the lactiferous ducts produced by the child each time it begins to nurse until the nipple is elongated sufficient to fill the child's mouth and to allow it to swallow without losing its hold. There is a constant jerking, with friction between the tongue and nipple. Acting on this theory, I have directed the mother or nurse to manipulate nipple and areolæ between the thumb and two fingers, using vaseline and drawing gently outward for about a minute. The child is then put to the breast and nurses gently, saving the mother that agonizing pain which is generally experienced in a case of short nipples. I have yet to hear of a case where the pain has not been relieved by this method, and I have seen deep fissures heal in a few days after this relief from pain. If mothers were treated for retracted nipples immediately after confinement, there would be few cases of sore nipples; and as long as the women of the present day will not recognize the evil effects of the corset, there will exist this condition of short nipples.—*New Eng. Med. Monthly.*

THERAPEUTICS.

The Food Value of Real Graham Bread.

Dr. Bardet (*Medical Week*) says: There is at present a marked tendency to return to the use of natural or Graham bread, made out of the whole grain. This tendency should be encouraged on dietetic and therapeutical grounds, because bread made in this way contains 40 instead of 20 per cent. of gluten, and contains twice as large a proportion of certain salts, particularly the assimilable phosphates, as that found in white bread, while it also contains the laxative fatty matter of the germ, which has been removed from the latter. These are indisputable advantages which it behooves us to utilize, at any rate in certain cases.

There is no doubt, for instance, that this bread furnishes vegetarians and the poorer classes with a much needed addition to their nitrogenous food Persons who are constipated, either by temperament or diet (milk diet, for example), will also derive great benefit from the use of Graham bread, owing to the laxative properties of the wheat oil. On the other hand, it would be a decided error to recommend its use to persons who are accustomed to an abundant meat diet, because in their case it would constitute an alimentary excess.

In order, moreover, to be really beneficial, Graham bread must be made of true Graham flour, consisting of the whole grain, especially the bran, finely ground up together, instead of being merely a mixture of bran, rye and ordinary flour, which unfortunately is what is usually sold under that name. It is very easy, however, to recognize the true Graham bread by its homogenous substance, without visible particles of bran, and its distinct, pleasant wheaten odor.—*N. A. Practitioner.*

PHYSIOLOGY.

The "Soul" Has Lost its Seat.

The abstract theory advanced by "Descarles" that the pituitary gland is the seat of the soul has at last been exploded, and the proper functions of the gland demonstrated almost beyond a doubt. A summing up of the researches of many experiments upon the lower animals and of observed symptoms in human beings in whom the pituitary body presented pathological conditions, upon section, goes to show that the pituitary is a trophic gland to the nervous system, regulating the chemical composition of the ventriculo-spinal fluid by supplying needed neutralizing acids and eliminating the products of oxidation and metamorphosis.

In rabbits deprived of the gland and in human beings where the gland had undergone pathological changes a marked swelling of the head and thickening of the skin with trophic changes, "akromegali," were observed. The following additional symptoms indicating auto-intoxication of the organism from deficient cerebral metamorphosis and elimination of the products of oxidation were observed in human beings: 1. Headache (frontal); 2. Sense of suffocation; 3. Digestive disturbances; 4. Eye symptoms, first in one, then in the other eye, such as amblyopia, hemianopia, permanent or intermittent amaurosis, strabismus, ptosis and exophthalmia; 4. Dullness and apathy; 5. Impaired memory; 6. Motor disturbances of the muscular system; 7. and, finally, death by coma.—*Pacific Med. Jour. Trans.*

ORIGINAL ARTICLES.

PLASTIC SURGERY IN GYNECOLOGY.

JOSEPH PRICE, A. M., M. D., PHILADELPHIA, PA.

The practice of surgery in all its branches requires a mechanical trend and an ability to devise means to accomplish a given end. All surgery is a species of civil engineering. It is a means of overcoming deficiencies or derelictions in the animal mechanical economy. If nature has been faulty in her distribution of the raw material, surgery comes to her assistance and adjusts the mechanical balance of affairs, as in the club foot, hypospadias, cleft palate, or wry-neck. If there has been an accident to the economy, surgery steps in with the engineering problem to be solved, what is to be removed and what is to be repaired, or what new means is to be found to regain a lost function or repair a damaged one. Now in all this it is evident that the mechanics of the part affected must be thoroughly understood before its repair can be accomplished, or intelligently undertaken. Once understood, a function may be imitated mechanically; artificial legs can run a bicycle or a foot race, and artificial hands accomplish many of the nicest manœuvres. Without such understanding all surgery or indeed any mechanical process is merely experimental and its results but tentative. Herein lies the fault and the failure of many of the mechanical and operative devices in the so-called improved methods of operations.

It requires no surgical genius to stitch a testicle in the inguinal canal in order to cure a hernia, or to perform some similar flighty trick that is novel and idiotic. But this is not surgery. The argument may be followed out indefinitely.

To do efficient plastic work in gynecology, a careful study of the anatomy and physiology of the parts injured and to be dealt with is necessary. Just as the scientific understanding of the mechanism of normal delivery has developed the scientific obstetrical forceps under the name of "Axis Traction," with the consequent diminution of the accidents of labor hitherto observed, so the study of the function of the parts often unavoidably damaged, renders their repair a matter of exact science modified only by the skill of the operator. The mechanism of perineal resistance and fracture is not a matter of chance, and the parts to be restored to function must be replaced in as nearly their physiological condition as possible. A heaping up of tissue here or a splitting there, although simulating a relay of opposing structure, does not necessarily mean strength, and it often happens that the advantage gained is apparent, not real.

Let me then insist that in order to mend a perineum intelligently, the mechanism of labor must be understood and the lines of fracture appreciated. The perineum does not break haphazard but always in well-defined lines, save under instrumental violence, and when tears are due to this

cause they must be dealt with as lacerated wounds anywhere else. The anatomical fractures due simply to obstetric force and resistance must be mended in the lines in which they occur.

Looked at from this standpoint the multitude of operations devised for the repair of the perineum is strangely grotesque. In no other part of the body has so much been attempted with so little scientific knowledge, unless we except that fools' paradise, the abdomen. Operation after operation has been suggested, with this or that name attached to it, without a shadow of justification for existence in the scientific literature of the day. Unfortunately, however, a name often goes as great a distance in surgery as on a forged note, and the operation gains prestige not from its merit but from its introducer. It is not my intention to hold up any special operation to ridicule, but rather to insist that any operation having for its end the remedy of a mechanical deficiency, shall have for its foundation a firm scientific principle and not simply a plausible plea that it brings about a condition which *simulates* the normal. By this it should stand or fall, as it would at once disclose whether it be a really valuable procedure or merely a specious simulation. Without such criterion, it will be necessary to make a careful comparative study of the methods proposed. Meanwhile the younger operator is left floundering in the whirlpool of discussion and claims, while the unfortunate patient is suffering all the inconveniences of experimental surgery. Here let it be formulated that an operation or procedure justified by scientific deduction is never reprehensible; and that the merely experimental procedure should be frowned upon, unless the condition of the patient is so bad that any operation, whatever, must improve her and be a relief.

Under the present abdominal regime of surgery, perineal and plastic work bids fair to become a lost art. The general practitioner is led to look inside the abdomen for all the evils of a woman's flesh, while, too often, it lies in injury done to the bladder or perineum or cervix during labor. Neglected cervical tears do much to render pelvic surgery necessary, while, on the other hand, indiscriminate *cervical* surgery often emphasizes previous *pelvic* disturbance and renders operative interference necessary. Hence will be seen the necessity carefully to discriminate between cases that operation will improve and cases that it will render worse.

In cases of serious pelvic invasion with accompanying lacerated cervix, it is often better, or imperative, first to do the pelvic operation and to follow this, *at another time*, with the cervical repair. I unhesitatingly condemn the plan advised by some to perform internal and external operations at one sitting. Surgery has not for its object the experimental determination of how much endurance the surgeon may possess, nor of how long the sufferer can stand anæsthesia without collapse. That "enough is as good as a feast," is nowhere truer than in the surgery of gynecology. There is enough discomfort incident to the surgery of any one or two of the simpler procedures, without heaping upon this the pain and danger of an abdominal operation.

Apart from the growing discomforts of neglected perineal and cervical lacerations, it must be remembered that the existence of a damaged and defective perineal structure conduces to future difficult and sometimes dangerous labor by predisposing to failure of rotation of the head. In reference to injuries of the cervix, it is always to be remembered that serious laceration of this structure is frequently a cause of after-coming malignant disease, of subinvolution, sterility, congestion and the like; often putting the patient in a condition of chronic invalidism from pain, menorrhagia, dysmenorrhea, displacement and mechanical derangements exhibited in relation with the bladder and rectum.

I have sufficiently dwelt upon the scientific and physiological conditions calling for attention to the surgery of these parts, and have made plain from a scientific standpoint what the requirements of plastic gynecological surgery are. My own practice in this branch of surgery has been to test, as far as possible under the lines laid down, what has seemed to be an advance in the surgery already at command. I regret to say that in many instances my only conclusion has been that I have wasted time and done something my good sense should have forbidden, but after all the good may lie in this—that my own experience may be of use, as here, in suggesting what ought not to be done, teaching negatively by contrasting forbidden

methods with others that have been uniformly successful and beneficial to the patients.

I have reminded you that perineal tears always occur at certain parts of the perineal structure. Without going into the anatomy of the parts or into a discussion of the reason for this fact, it is sufficient to remember, as each one of us with a practical experience must, that these tears are either lateral under the ramus of the pubes, or central extending from vagina toward the rectum. The tears toward the rectum tend to run around it rather than through it, owing to the differentiation of structure in these two tubes. Now, it is to be remembered, that the tears of the vagina are always from within outward, from above downward, and that therefore the external or skin operations for perineal lacerations are essentially non-scientific procedures. All operations for the restoring of the integrity of these parts should be done in the lines of their destruction and, *therefore, from within outward and from above downward.* When the skin of the perineum is involved, mending of this is merely a cosmetic procedure. The cosmetic element too often predominates in many of the so-called perineal devices.

In examining a perineum to determine whether it has been ruptured or not, a mere ocular inspection will not answer. A central tear is almost always visible. Not so a lateral sub-ramic laceration. To detect this the finger should be introduced into the vagina, when the laceration will be determined by the fissure caused by the separation of tissue on one or both sides. The early, prompt, and, if possible, the immediate repair of these tears is to be advised under surgical rules applicable elsewhere in the body. If the patient happens to be too ill or too weak to endure surgical interference, operation is not to be insisted upon. Discretion is to be used here as elsewhere in deciding cases.

The silk-worm-gut with shot is by far the most preferable material to be used for sutures. As little tissue as possible is to be included within the ligature, and strangulation is to be avoided. Early operation precludes the necessity for clipping away even the minutest bit of tissue, and the parts are usually very prompt to heal. When the sphincter ani has been involved, care must be taken to bring the ends of the muscle into apposition. To accomplish this a special stitch is necessary which I shall demonstrate in the discussion. So far as the method is concerned, it is evident to you all that the one suggested is that of Emmet. His procedure stands preëminent among the scientific suggestions and methods of modern gynecology. Its logic is unassailable, and its results cannot be fairly challenged. His work is as delicately true and accurate as an Italian mosaic, while his technique is so simple that to follow it needs only commonplace attention. His demonstration of the scientific value of his method is as accurate as that of any mathematical proposition, and criticism of the ends obtained, or of the method pursued, arises either from ignorance or misunderstanding.

In old tears the method and lines of denudation as indicated in Emmet's own book, are unfortunately obscure. This fact I believe in a measure explains the reason of the operation having so long been questioned, criticised and misunderstood.

Anemia.

Syphilis among the Esquimaux.

It has been generally believed that the Esquimaux were immune against syphilis, as no case was observed in one hundred and fifty years, although the infection was known to have been repeatedly taken to Greenland by sailors. After the year 1872 fifty cases were observed amongst the natives of the villages of Foighet and Arsuk; in 1889 only ten cases were observed, while there have been none since 1890. Helms, in discussing the subject, attributes the rarity of the disease to a diminished susceptibility on the part of the natives. Other medical men equally versed in the pathology of the Esquimaux are inclined to ascribe the extinction of syphilis to the treatment and severe hygienic measures adopted by the Danish government, including the isolation of the infected village.—*Universal Medical Journal.*

THE INJECTION TREATMENT OF HERNIA; WITH FORMULA FOR FLUID.

W. H. WALLING, M. D., PHILADELPHIA, PA.

This method of treatment was first experimented with by the elder Pancoast, in 1836. He used the tincture of iodine, and the reaction was so disastrous that the profession very justly condemned the whole procedure. Later on, Heaton, of Boston, and still later, Warren of the same city, reported numerous cures. Their injections not being of a proper character, and not asceptic, and their methods crude, violent inflammations resulted, confining their patients to their beds, if nothing worse. Again was the practice condemned. Others followed in Heaton's footsteps, some however, using still more powerful chemicals, such as sulphate of zinc, iodine, carbolic acid, and even the strong mineral acids, and with like disastrous results.

The method has, however, been again brought forward, but upon a strictly scientific basis.

The treatment of reducible hernia is a very profitable branch of minor surgery that has been almost entirely lost to the medical profession. Fully one-tenth of the population suffer from rupture. Physicians have allowed nearly all of this rich clinical material to go directly to the truss makers, because they could do no more than the truss maker—simply fit a truss.

Such cases may now be reclaimed to the profession by adopting the injection treatment, with a proper fluid, and a suitable syringe. This method is receiving the attention of, and being adopted by, progressive physicians all over the country.

Chemistry has come to our aid in this matter. Substances that are in themselves harmful or obnoxous, by combining them with other substances, or by arranging their elements differently, become useful therapeutic agents or agreeable preparations, as the case may be. Take the oils of rose and the oil, or spirits of turpentine, as examples of elemental arrangement. Both are hydrocarbos. The first has the formula C_{16} H_{34}, the latter, C_{10} H_{16}. This shows the vastly differing products resulting from a different arrangement of their elements.

Then, too, we have new products, from the laboratory; preparations that but a short time ago were scarcely dreamed of, and that are now well nigh indispensible.

Chemistry and surgery, that was accepted ten or twenty years ago, is too far behind the age to be allowable now. Text books not more than five years old, are, in many respects, worthless, so rapid have been the advances.

Applying all this to the treatment of hernia, we find, by using improved instruments and methods, that reducible hernia may be quickly and easily cured without danger, with little discomfort to the patient, and no loss of time; the essentials being a deft hand, a proper fluid, and a trocar and canula syringe, that I have devised for this especial purpose. The technique of the operation for inguinal hernia is as follows: Place the patient on the operating table, reduce the protrusion, if out, wash the parts well with some antiseptic solution, invaginate the scrotum with the index finger and locate the external ring; inject into the skin, at this point, five or more minims of a five per cent. solution of cocaine, to which has been added one drop of a one per cent. solution of nitro glycerine. (Granules of cocaine and glonoin are very convenient for this purpose. Boil the water in a spoon, dissolve the granules in the required amount and inject.) Have the hernial syringe filled with fluid, displace the air, wipe off the drop of fluid that may appear at the needle's end, and carefully note how far the canula must be turned off, in order to entirely cover the needle point. Allow three minutes for the cocaine to take full effect, and having drawn back the canula, exposing the needle-spear, thrust the instrument through the skin and fascia at the point of the cocaine injection. Push it well into the external ring, carefully avoiding the cord. Change the instrument to the other hand, and again invaginate the scrotum, and be sure that the

needle has entered the ring. Then screw down the canula until it covers the point of the needle, and, dipping down with the instrument, pass the canula, by gentle manipulations up the canal to the inner ring. In doing this, bear in mind that the inguinal canal is from one and a half to two inches in length, lying nearly parallel with Poupart's ligament, and about one-half an inch above it.

Having reached the inner ring, slowly inject from three to five minims of fluid, a minim at a time; wait one or two minutes, slightly withdraw the piston of the syringe in order to empty the needle, and withdraw the instrument. Gently massage the parts to evenly distribute the fluid. Cover the puncture with antiseptic collodion. There will be more or less of a burning or smarting sensation experienced by the patient, but by lying quietly for a few moments it will pass off. It may return for a short time when the truss is adjusted, which must be done before the patient rises from the table. He must also be instructed to take off the truss only after lying down at night, and put it on before arising in the morning.

Repeat the operation every five or seven days, according to the amount of fluid used, and the degree of reaction. There will be some soreness for a day or two and the patient must be told this. A certain amount of healthy inflammation must be set up and maintained for a sufficient length of time, in order to effect a cure. From six to twelve injections usually suffice. The older the patient, the longer the time required. A well fitting truss must be adjusted and worn for a few days before operating, in order to see if it keeps the hernia well reduced.

The fee for treatment ranges from $25 to $100, or more, according to the case and the ability to pay; one-half to be in advance. A double rupture should be double pay. In treating these, alternate the injections, first one side, then the other, so as not to produce discomfort. The charge for fitting a truss should be not less than $10, to be paid at once.

Any physician may soon become expert in the above operation. There is absolutely no danger whatever if a proper fluid and instrument be used. In all my cases I have not had a single dangerous symptom, or one bordering on that line. It is well, however, to commence with a minimum dose, and increase as may be indicated.

With an ordinary hernia, in a vigorous, healthy individual, after the sixth injection the treatment may be suspended for a few weeks; then test the parts by taking off the truss, allowing the patient to stand up, and thus determine whether any further injections may be necessary. The truss should be worn for from three to six months after treatment ceases.

In some forms of rupture, where the canal has become obliterated, as well as in old or very fat patients, it may be advisable not to lay aside the truss at all.

Rupture in children is sometimes cured with a single injection. The dose with the little ones must be light.

The fluid that I use has the following composition:

℞

Complex Salts of Aldehyde	30	per cent.
Iodo-Ethylate of Guaiacol	30	" "
Sulpho-Tannate of Zinc	20	" "
Free Guaiacol	5	" "
Beechwood Creasote	15	" "

These rare and delicate chemicals are separately prepared, then carefully combined and dissolved in an antiseptic medium, in strict conformity with their respective affinities and dosage. Injection dose, three to five minims.

I use the same fluid in the treatment of hydrocele and varicocele. Rinse out the syringe and needles with alcohol; never with water. Do not allow water to come in contact with the fluid; water decomposes it.

Permanganate of Potash as an Antidote to the Cyanides.

Dr. J. V. Kossa (*Central-Blatt f. d. Medicinischen Wissenschaften*, No. 17, 1894,) from experiments on animals claims that the permanganate of potash is an efficient antidote to hydrocyanic acid and the cyanides. A dose of over ten times greater than the fatal one was given to rabbits and immediately followed by the permanganate; no symptons of poisoning followed. The potash salt oxydizes the poisonous compounds into innocuous preparations.—Translated for the MEDICAL AND SURGICAL REPORTER by the Translator, F. H. Pritchard, A. M., M. D.

COMMUNICATIONS.

THE ETIOLOGY, PATHOLOGY, AND TREATMENT OF INTESTINAL FISTULA AND ARTIFICIAL ANUS.*

N. SENN, M. D., PH. D., LL. D.†

A correct appreciation of the causes which give rise to the formation of intestinal fistula is prerequisite for the adoption of appropriate treatment. The term intestinal fistula will be used in this paper to signify a communication between the lumen of any part of the intestinal tract and the surface of the body or with any of the hollow abdominal or pelvic viscera. A practical distinction must be made in regard to the size and character of such abnormal communication into 1, fistula; 2, artificial anus. The difference is one of degree and not of kind. Speaking from a purely surgical standpoint, a fistula of the bowels is an opening through which gas or only a part of the liquid and solid intestinal contents escape, while an artificial anus implies a complete interruption of the fecal circulation at the abnormal outlet. The latter condition is determined either by the size of the defect in the intestinal wall or the existence of mechanical conditions which divert the intestinal contents in the direction of the abnormal outlet and away from the distal side of the bowel. The mechanical conditions which thus divert the fecal current are either a flexion or the presence of a spur or septum at a point opposite to the abnormal outlet, caused by the projection of the intact part of the intestinal wall in the direction of fistulous opening. The surgeon aims to produce such an obstruction to the fecal circulation when he desires to procure rest for the distal part of the intestinal tract by the formation of an intentional artificial anus. The amount of intestinal contents which escapes from the intestinal canal through such an abnormal outlet depends less on the size of the opening than the existence of one or both of the above mentioned mechanical conditions. If the intestinal tube is straight or only slightly curved, even a large opening may resemble a simple intestinal fistula, while on the other hand, a small opening associated with a flexion, or a well-developed spur, appears clinically as an artificial anus and must be treated as such. The internal fistulæ communicate most frequently with another part of the intestinal tract, the bimucous fistula of Dreshfeld with the bladder, vagina, and uterus.

ETIOLOGY. Intestinal fistulæ are divided into: 1. Intentional. 2. Accidental. The surgeon occasionally resorts to the formation of an intestinal fistula or artificial anus, in the treatment of inoperable mechanical obstruction, by resorting to a colostomy or enterostomy, according to the location of the mechanical obstacle which has necessitated the operation. If in such cases the intestinal opening is to serve only a temporary purpose, it is closed by operative measures in the same manner as will be advised in the discussion of the operative treatment of accidental fistula, after the distal part of the intestinal canal has been rendered permeable spontaneously or by subsequent operative interference.

Accidental fistulæ are produced, according to the immediate cause, by: 1. Gunshot and stab wounds of the abdomen. 2. Submural injury of the bowel. 3. Ulceration of the bowel. 4. Strangulation of bowel. 5. Foreign bodies in intestinal canal. 6. Malignant tumors. 7. Intestinal actinomycosis. 8. Pelvic and other abdominal abscesses. 9. Appendicitis. 10. Unintentional injury to the bowel during abdominal and pelvic operations. 11. Ligatures. 12. Sutures. 13. Drainage tubes.

GUNSHOT AND STAB WOUNDS. These injuries usually result in fatal septic peritonitis if the intestinal wound or wounds are large enough to permit escape of fecal material into the free peritoneal cavity, and not subjected in time to the direct operative treatment. A fecal fistula, ex-

* Inaugural thesis before the Gynecological Society of Chicago, June 15th, 1894.

† Professor of Practice of Surgery and Clinical Surgery in Rush Medical College; Professor of Surgery, Chicago Polyclinic; Attending Physician, Presbyterian Hospital; Surgeon-in-Chief St. Joseph's Hospital, etc., Chicago.

ternal or internal, may result if the wound is small or if only a part of the intestinal wall has been injured, in which event the injured part becomes adherent to the parietal peritoneum or an adjacent hollow organ. A resulting circumscribed abscess may later under such circumstances, perforate the abdominal wall or discharge its contents into the adherent organ and thus establish either an external or internal fistula. According to the experience of surgeons during the War of the Rebellion, such an occurrence is more likely to follow injury of the colon than wounds of the small intestines.

SUBMURAL INJURY. Partial laceration of the intestinal wall without a penetrating wound of the abdomen occasionally results in circumscribed peritonitis, caused by the migration of pathogenic microbes from the intestinal canal through the damaged wall to the surface of the bowel, where, if present in sufficient number, they may produce an abscess which not only completes the intestinal perforation, but may result at the same time in the formation of an external or internal fistula. Such fistulæ are usually small and close spontaneously in the course of time. In suspected submural injury of the bowel without evidences of complete rupture and fecal extravasation, it is of the greatest importance to enforce efficient treatment with a special view of preventing this remote complication.

ULCERATION. Ulceration of the bowel is frequently followed by the formation of an intestinal fistula if the free peritoneal cavity is shut off by adhesions before perforation takes place and the ulcer manifests no tendency to repair. In the upper part of the intestinal canal the round, perforating ulcer of the duodenum may produce such a result. I have observed two cases of perforating typhoid ulcer in which a diffuse abscess formed which was freely incised and drained. In one case the abscess cavity contained at least a quart of fecal material which had evidently been accumulating for more than a week. The patient's general condition was such as to contraindicate search for and suturing of the perforation. In both cases life was prolonged from one to two weeks, but the patients finally succumbed to sepsis. I can readily conceive that under more favorable circumstances such patients might recover under similar treatment with an intestinal fistula which would in all probability heal spontaneously or could be closed later by operation with a good prospect of success. From my own personal observation I am satisfied that the ulcers which terminate most frequently in the formation of an intestinal fistula are of a tubercular character. I have observed a number of such instances.

The clinical course in such cases is almost typical. The localized peri-intestinal process is usually preceded by symptoms which point to a chronic catarrhal or ulcerative enteritis. A painless, cold abscess appears at the point where the perforated bowel has become attached to the abdominal wall. The abscess develops insidiously and progresses very slowly. If the abscess opens spontaneously or is incised, it contains, as a rule, no fecal material. The fistula forms later, or is produced at once if the granulations lining the abscess wall are scraped away with a sharp spoon. The communicating opening between the lumen of the bowel and the abscess cavity is temporarily blocked with granulations which, when removed or when destroyed by suppuration and degeneration, establish the fistula through which gas and fecal contents escape. In one case I found such an abscess in the umbilical region, and in another in the right linea semilunaris. In both cases a fecal fistula was established, and the patients eventually died from the effects of the primary intestinal infection. Such fistulae hasten the fatal termination and are not amenable to successful surgical treatment. Tubercular abscesses in communication with a perforated intestinal tubercular ulcer should not be incised. The proper treatment for such cases is tapping of the abscess, followed by injection of iodoform emulsion, a form of treatment which will postpone, if not prevent, the formation of intestinal fistula. König is of the opinion that in many cases of tubercular intestinal fistula the primary disease starts in the peritoneum, resulting in perforation of the intestine from without inward. In such cases multiple fistulae are often established in rapid succession.

STRANGULATION. The functional disturbance of the intestine following strangulated hernia, terminating in gangrene without treatment or under conservative measures, will depend upon the extent of loss of mural tissue, and will vary from a

small fistula only large enough to permit the escape of gas to a perfect artificial anus. Occasionally such an accident follows the reposition by taxis of a damaged intestinal loop. The Littre, femoral and properitoneal herniæ are most likely to be overlooked by the surgeon, and consequently most frequently give rise to this complication.

FOREIGN BODIES. Perforation of the intestinal wall by a foreign body, preceded by a circumscribed plastic peritonitis, frequently results in the formation of an abscess which, when it reaches the surface or an adjacent hollow organ, is followed by an intestinal fistula. Small, slender foreign bodies, such as needles, pins and fish bones, often perforate the intestinal wall and find their way to the surface or into neighboring organs without giving rise to an intestinal fistula. In one case I removed four fish bones from a small abscess in the median line below the umbilicus, after which the abscess healed promptly and permanently. The foreign bodies which are most frequently found in abscesses preceding intestinal fistula are sharp fragments of bone, gall stones, and enteroliths.

MALIGNANT TUMORS. Malignant tumors may cause intestinal fistula either by producing obstruction followed by distention and ulceration on the proximal side or by directly implicating the intestinal wall. The latter mode of origin is the most common. The malignant tumor in such instances invades by contiguity the part or organ which becomes the seat of the intestinal fistula, and at the same time perforates the intestinal wall, so that the fistula is surrounded everywhere by malignant tissue. Carcinoma more frequently pursues such a course than sarcoma. Infection of the malignant tumor with pus microbes plays often an important role in such cases. The supperative infection often overshadows the malignant disease so completely that the surgeon is misled in his diagnosis, and institutes treatment appropriate for abscess when the operation reveals a malignant tumor as the foundation of the difficulty. Carcinoma of the cecum complicated by suppuration has been repeatedly mistaken for appendicitis. Carcinoma of the sigmoid flexure and cecum occasionally results in a pathological anastomosis between the affected part of the bowel and an adjacent loop of the small intestine. Carcinoma of the upper part of the rectum only too often invades the bladder and results in the formation of a recto-visical fistula. Carcinoma of the stomach and transverse colon has resulted in pathological grastrocolostomy.

ACTINOMYCOSIS. A number of cases of intestinal actinomycosis have been recorded in which the disease in its course perforated the intestinal wall and gave rise to diffuse abscesses and intestinal fistula. The ileo-cecal region is the favorite locality for such processes. In the only case of this kind that came under my own observation the disease originated evidently in the ileo-cecal region, but the abscess reached the cavity of Retzius and was opened in the median line above the pubes.

PELVIC AND ABDOMINAL ABSCESSES. By far the most frequent cause of intestinal fistula is pelvic and abdominal abscesses. Such abscesses sometimes are caused by migration of pyogenic microbes through a damaged or inflamed intestinal wall, perforating later the intestines, and finally open or are incised on the surface when the fistula is completed. The fistulous tract is often long and tortuous. More frequently a pyosalpinx or acute phlegmonous abscess of the parauterine connective tissue pursues such a course. Such abscesses open most frequently into the rectum, bladder, and intestinal coils upon the floor of the pelvis, but they may open into the cecum and sigmoid flexure. Externally they point most frequently in the groin, but they may also reach the surface through the sacro-sciatic notch and occassionally extend to the lumbar region. The external fistulous opening may be found in any of these localities. Not an infrequent cause of intestinal fistula is tubercular abscess resulting from tubercular spondylitis and tuberculosis of the pelvic bones. In some cases the abscess is discharged first into the cecum or rectum; less frequently into other parts of the large and small intestines, and later reaches the surface; or the fistula forms in the course of suppurating tubercular tracts. Rectal insufflation is an exceedingly valuable diagnostic test, not only for the purpose of ascertaining whether or not the fistulous tract communicates with the intestine, but also in demonstrating the exact location of the intestinal perforation.

APPENDICITIS. Appendicitis is the most frequent cause of intestinal fistula in the illeocecal region. The fistula is produced in one of two ways: 1. Sloughing or perforation of the appendix. 2. Rupture of an abscess of appendical origin into the secum or adjoining intestinal loops, with the subsequent formation of an external opening. If the entire appendix is cast off as a slough with the contents of the abscess in gangrenous appendicitis, the fistulous opening involves the cecum and occupies that part of the bowel to which the appendix is attached. Clinically such a fistula resembles a cecal fistula produced by other causes. In partial gangrene of the appendix and perforation of the organ, treated upon the expectant plan by incision and drainage without removal of the appendix, if a fistula persists, the remaining lumen of the appendix communicates with the cecum on one side and the external fistulous tract on the other. The fistulous opening into the bowel under these circumstances is so small that seldom anything else but gas escapes. Such fistula occasionally heals; spontaneously in the course of a few weeks; but after it has become well established, closure of the fistula without operation is not to be expected. A paratyphlitic abscess rupturing into the cecum often terminates into a permanent cure, but sometimes it results in extensive destruction of the cecal wall followed by the formation of a correspondingly large fistulous opening. The location of the cecal opening will vary according to the situation of the abscess. The cases of cecal fistula which have come under my own observation involved either the anterior or posterior wall; but they may affect any part of cecum, and occasionally the abscess ascends in the direction of the ascending colon, which it may peoforate and cause a fistula of this part of the large intestine. I have seen three cases of fistula of the cecum following appendicitis in which the opening of the abdominal wall and cecum was large enough to insert three fingers. In all these cases the fecal current was arrested at the opening by the presence of an effective spur formed by the projection of the opposite wall toward the opening in the cecum. It is in cases of this kind, if the abscess has been opened by the surgeon, that he is credited by the patients and friends with having cut the bowel, when in reality the intestinal opening either was present at the time the operation was made or occurred later by sloughing of the inflamed cecal wall.

INJURY OF BOWEL DURING ABDOMINAL AND PELVIC OPERATIONS. Under this head it is not my intention to discuss those gross lesions of the intestines occurring during abdominal and pelvic operations which the surgeon recognizes at once and resorts to the necessary treatment. I wish more particularly to refer to overlooked and incomplete wounds of the bowel as causes of intestinal fistula. Modern gynecology encourages heroic attempts in the removal of abdominal and pelvic tumors that only a few years ago would have been regarded as inoperable by the boldest surgeons. The removal of adherent tumors and pus tubes brings the operator often in very close contact with the intestines. The inflammatory processes which have produced the firm adhesions have often resulted in great damage to the adherent part of the intestine. The intestinal wall, from pressure, cicatricial contraction, and impaired nutrition, is often found not much thicker than ordinary writing paper, hence exceedingly liable to be torn during the separation of firm adhesions. The intestine attached to a tumor or pelvic abscess by firm and old adhesions has lost its outer or peritoneal coat over an area corresponding with the extent of the adhesions. Unless the surgeon practices the necessary precaution of making the detachment at the expense of the tumor or tube, if he does not tear an opening into the bowel he will, at least, seriously damage the intestinal wall. I have no doubt that in numerous instances of this kind surgeons have overlooked minute perforations in the bowel which, if they did not result in fatal septic peritonitis, became the direct source later of an intestinal fistula. It must also be remembered that a greatly damaged intestinal wall is permeable to pyogenic microbes, and consequently becomes not infrequently the sole cause of a late infection after laparotomy, and if the patient survives, of abscess and intestinal fistula. Every experienced surgeon will recall to his memory such mishaps when he could assure himself that in other respects the operation was faultlessly performed. The examination of detached intestinal loops for perforations or other serious damage should not be postponed

until completion of the operation, as it may be impossible to find them again at that time. The inspection should be made at once and all defects remedied before additional adhesions are separated. By pursuing such a course, and by detaching the adhesions at the expense of the part to be removed, we will hear less in the future of septic peritonitis, abscess and intestinal fistula arising from this cause after laparotomy.

LIGATURES. In small wounds and limited gangrene of the bowel Astley Cooper made a small cone, the apex of which corresponded with the injury or disease, and applied a ligature of fine silk around the base. The ligature cuts its way into the lumen of the bowel during the time the resulting defect becomes sealed by plastic lymph. We can readily conceive under what circumstances such a procedure would prove safe and efficient. If the parts included in the ligature and the ligature itself are aseptic the formation of a fistula is prevented by the production of new tissue around the ligature and included mass before the ligature reaches the lumen of the bowel. If, on the other hand, the asepsis is not perfect, and suppuration occurs in the track of the ligature, an intestinal perforation is very likely to ensue.

After separation of an adherent intestine bleeding points are often tied with silk. Isolation of the bleeding vessel is usually out of question, and more or less of bowel tissue is included in the ligature. It must not be forgotten that under such conditions the bowel has been deprived of its peritoneal investment, and consequently the facilities for encapsulation of the ligature are diminished. If to this is added an extremely attenuated bowel wall, it is not difficult to understand in what way a ligature may sometimes give rise to a late perforation, peritonitis, abscess, and intestinal fistula.

SUTURES. Careless suturing of the abdominal incision is responsible for many accidents to the intestines. Undue haste in completing this part of the operation is often severely punished. Unless the operator resorts to proper precautions the needle may transfix a part of the circumference of the small intestine; on tying the suture the loop is anchored against the external incision, the ligature later cuts it away through the included part of the bowel, and if a fatal peritonitis does not result an intestinal fistula is sure to follow. I have seen two cases of intestinal fistula, in the practice of distinguished surgeons, where I had reason to believe that the intestinal fistula had such an origin. But this is not the only way in which sutures have produced this complication. In tying the sutures a loop of the underlying intestines may be caught between the suture and the abdominal wall, and on tightening the suture strangulation results, followed by intestinal obstruction, gangrene of the strangulated part of the bowel or coil, abscess and fistula. Again, an intestinal coil may escape between the sutures and become strangulated between the margins of the wound with similar consequences. It is time that surgeons should recognize the suture as a cause of such complications and resort to efficient prophylactic measures. I am strongly convinced of the value of a separate row of buried absorbable peritoneal sutures in closing the abdominal incision, both for the purpose of guarding against accidents to the intestines and as a prophylactic measure against ventral hernia. Whenever it is possible the omentum should be drawn downward far enough to cover the entire length of the incision. The use of the aseptic compress as an aid in suturing the external wound is so well known that it is only necessary to mention it in connection with my subject.

DRAINAGE TUBES. The last, but by no means the least important subject which I shall discuss in connection with the etiology of intestinal fistula is the drainage tube. Prolonged tubular drainage with glass or rubber tubes is a well-known factor in the production of intestinal fistula. The opening in the bowel is produced by pressure atrophy. I am inclined to believe that the elastic pressure caused by rubber drains is more injurious than that exerted by glass tubes. Long-continued tubular drainage for suppurative lesions is more dangerous in this respect than similar methods of drainage for parenchymatous oozing or other aseptic pathological conditions. In the former case the suppurative inflammation along the drainage canal adds to the destructive effect of pressure. It will be difficult, if not impossible, to entirely eliminate this etiological element by any amount of care

in cases requiring long-continued tubular drainage. In recent cases necessitating drainage for a few days I have been in the habit of surrounding the glass or rubber drain by a few layers of iodoform gauze, for the purpose of diminishing the harmful effects of localized pressure. In drainage for suppurative affections it is advisable to gradually reduce the size of the tube for the same reason, and whenever practicable interpose between the intestine and tube a few layers of iodoform gauze.

TREATMENT. The treatment of an intestinal fistula must have for its aim closure of the abnormal opening with as little interference as possible with the lumen of the bowel. The statement has been made, and is borne out by clinical experience, that many intestinal fistulæ close spontaneously. This favorable termination may be expected in cases in which the opening in the bowel is small, the immediate cause of a benign and temporary character, the general health of the patient not much impaired, and the fistulous opening in the bowel so located that it can readily become attached to the parietal peritoneum or the serous investment of an adjacent organ. The spontaneous healing of an intestinal perforation is always followed by permanent parietal or visceral adhesions. In fistulæ resulting from tuberculosis, malignant disease, and actinomycosis, spontaneous healing from the very nature of the primary cause, is out of the question, and in the majority of these cases operative treatment with a view of closing the fistula is contraindicated. The operative treatment in such cases deserves consideration only in the event that the primary cause can be completely eliminated before an attempt is made to restore the continuity of the bowel. In fistula caused by malignant disease, in which the extent of the primary cause has rendered a radical operation inapplicable, it may be advisable to secure rest for the diseased part of the intestine by establishing an artifical anus on the proximal side. In the treatment of tubercular and actinomycotic fistulæ the primary disease must receive proper attention, and, in case it is amenable to successful treatment, the fistula will heal spontaneously or is subjected later to appropriate surgical treatment. Before I proceed further to the discussion of the surgical treatment of intestinal fistula it is important to refer briefly to a few of the more important points of the

PATHOLOGICAL ANATOMY. For the sake of simplicity I will describe the different forms of intestinal fistula as we observe them on the surface of the body, although the same remarks will apply to the internal fistulæ where similar conditions are developed.

INTESTINAL FISTULA. Intestinal fistula as defined in the introductory remarks of this paper presents itself in one of two forms: 1. A fistulous tract leads from the surface to the opening in the intestine. 2. The mucous membrane of the intestine lines the fistulous tract and is continuous with the skin on one side and the mucous lining of the intestine on the other. In the first variety the opening in the bowel is more or less distant from the surface, and the tract is lined by granulations. In the second variety the intestinal wall reaches the surface and the margins of the opening in the bowel form the border of the external opening, the entire fistulous tract being lined by mucous membrane. In both instances the opening in the bowel is lateral, the intestinal tube either straight or slightly curved, presenting no mechanical impediments to the fecal current.

ARTIFICAL ANUS. The interruption, partial or complete, of the fecal current at or in the immediate vicinity of the fistula is usually due to one of three causes: 1. Intestinal obstruction below the fistula. 2. Flexion of the bowel at a point corresponding with the location of the fistula. 3. The presence of a spur opposite the opening in the bowel. If perforation of the bowel takes place in consequence of an intestinal obstruction, the cause or causes which have given rise to this accident maintain the obstruction and all of the intestinal contents escape through the fistula, which then serves the purpose of an artifical anus. If the perforated part of the bowel becomes flexed by adhesions or otherwise, the flexion narrows the lumen of the bowel and directs the fecal current toward the abnormal outlet. Under such circumstances a considerable part of the intestinal contents necessarily escapes through the fistulous opening. If the flexion becomes more acute the intestinal wall opposite the opening forms a spur which when fully developed completely

intercepts the fecal current and transforms the fistulous opening into an artifical anus.

From these remarks it necessarily follows that spontaneous healing can only be expected in cases in which the fistulous tract is not lined by mucous membrane and in which the fecal current meets with no impediment by flexion or spur formation. As the fistulous opening in the bowel is often beyond the reach of an examination to determine the actual conditions, time plays an important part to enable the surgeon to determine whether or not surgical interference is necessary. In the absence of an indicatio vitalis an operation should be postponed until the clinical course has demonstrated that Nature's resources are inadequate to accomplish the desired object. An early operation is demanded if the fistula involves the upper part of the small intestines and the escape of chyle endangers life from inanition. In the absence of such an indication, and in the absence of positive proof that spontaneous healing is impossible, conservative treatment should be continued until the indications for a radical operation are established. A carefully selected diet, attention to the condition of the bowels, rest, compression over the fistulous tract, and antiseptic treatment of the suppurating tract embrace the leading indications of the expectant treatment.

Surgical Treatment. The surgical treatment must be governed by the pathological conditions which characterize each individual case. A careful inquiry concerning the etiology and pathology in each case is therefore necessary in order to enable the surgeon to select the appropriate therapeutic resources.

Cauterization. Cauterization of the fistulous tract is useful not only in expediting spontaneous healing in cases in which such a result is to be anticipated, but also for the purpose of removing anatomical conditions incompatible with such a determination. Nitrate of silver is most efficient in stimulating the process of repair in cases in which the tract is lined by flabby, infected granulations. Benefit from this agent can only be expected if it can be applied the whole length of the canal. Its application is worse than useless if the entire tract is not accessible either on account of its length or tortuous direction. If the fistulous tract is lined by mucous membrane, is short and readily accessible in its whole length, the Paquelin cautery can be resorted to with advantage. The cauterization must be made deep enough to destroy the entire thickness of the mucous membrane. On separtion of the tubular eschar the fistulous opening is enlarged, and for a time more of the intestinal contents escape through it; but in a short time the canal becomes blocked by granulations, which eventually result in its closure. Before using the cautery the length of the tract must be carefully determined, in order to protect the bowel against injury from the point of the instrument. The same instrument is of value in the treatment of larger fistulæ lined by mucous membrane not complicated by mechanical impediments to the fecal circulation. I have resorted to this procedure in a number of cases of surface fistulæ lined by mucous membrane, and have been well satisfied with the results.

Drainage of Abscess Cavity. An abscess cavity interposed between the intestinal opening and the fistulous tract on the surface or in one of the pelvic organs, constitutes often an insurmountable obstacle to spontaneous healing. In many such cases the abscess cavity is imperfectly drained and is being continually contaminated by fecal material. If the abscess is so located that it can be safely and more efficiently drained, such a procedure will often accomplish all that is desired. This method of procedure is particularly indicated in the treatment of pelvic abscesses complicated by intestinal fistula. It must, however, not be forgotten that under such circumstances the organs in the vicinity of the abscess are often displaced by inflammatory adhesions and exposed to injury in efforts to secure better drainage.

Mechanical Repression of Spur. The spur has been recognized as a cause of the persistence of intestinal fistula for a long time, and different methods of treatment have been devised for its removal. Desault advised the insertion of a roll of charpie into the bowel with a view of increasing the size of the lumen of the bowel and of repressing the spur. Banks inserted a large rubber tube, which he fastened in the fistula, for the same purpose. As the formation of the spur takes place in consequence of the flexion of the bowel, we can readily understand why all such mechanical devices have proved of so little value.

REMOVAL OF SPUR. The first efforts to remove the spur by operative procedure were made by Schmalkalden in 1795. He removed the spur with scissors and knife. The disastrous results which must have necessarily followed this operation led Dupuytren to accomplish the same object by a bloodless method. He devised for this purpose a clamp, which he applied to the spur, and by tightening the screws connecting the branches made it cut its way through the tissues by causing linear necrosis of that part of the septum included in its branches. The instrument effects its object in from three to eight days. It is then again applied on the side of the linear section, and the same procedure is repeated until the spur is removed. The results of this operation were quite satisfactory before laparotomy was made a safer procedure.

In 1824 Dupuytren reported forty-one cases, of which number twenty-nine were cured and only three died. Later Heiman collected eighty-three cases with a mortality of 4.83 per cent. The most recent statistics collected by Körte comprise 111 cases with eleven deaths. In many of the cases, however, the fistula remained. After the removal of the spur the margins of the fistula were usually destroyed with the actual cautery. I shall show further on that the spur develops in consequence of flexion, and that if the flexion is arrested in the operative treatment of artificial anus its removal is superfluous. The recent advances made in intestinal surgery will render Dupuytren's operation obsolete in the near future.

CLOSURE OF FISTULA BY PLASTIC OPERATION. The closure of the intestinal fistula by plastic operation was introduced by Diffenbach. It was not his intention, by the operation which he devised, to close the opening of the bowel at once, but to cover it with a bridge of skin, leaving the closure to be accomplished later gradually by granulation. Between two elliptical incisions he excised the margins of the fistulous opening and the skins surrounding it. A bridge of skin is made by making on one side of the oval defect, and the necessary distance from it, a curved incision twice the length of the wound, and, by undermining the skin, a bridge is formed with which to cover the opening. The oval wound is closed by interrupted sutures. The operation leaves a crescent-shaped raw surface produced by sliding the bridge, which was left open to heal granulation. This operation, as well as plastic closure by pedunculated flaps, had their field of usefulness before addominal operations were rendered comparatively safe by an approved technique and the general adoption of aseptic precautions, but are seldom, if ever, resorted to at the present time.

SUTURING OF FISTULA WITHOUT OPENING THE PERITONEAL CAVITY. The closure of an intestinal fistula by vivifying its margins and suturing, without detaching the bowel or opening the peritoneal cavity, has not yielded very satisfactory results. The operation is only adopted for cases in which the intestine is attached to the abdominal wall and the fistulous opening is readibly accessible, and where no canalization impediments are present. I have succeeded in two cases in closing the fistula completely and perfectly by one operation.

In advising a resort to this, as far as life is concerned an absolutely safe operation, I must insist in the first place upon the necessity of freely excising the fistulous tract, removing all of the scar tissue and a circular strip of the mucous membrane lining the margins of the fistulous opening in the bowel, as well as the importance of bringing in accurate apposition the different anatomical structures by several tiers of buried sutures. A conscientious observance of these precautions will frequently reward the surgeon with success in closing an intestinal fistula by extra-peritoneal suturing.

INTESTINAL ANASTOMOSIS. The formation of an intestinal anastomosis in the treatment of an intestinal fistula is indicated in cases in which the extra-peritoneal methods are not applicable or have proved unavailing and the usual intra-peritoneal operations are contra-indicated. Under such circumstances the exclusion from the fecal circulation of the perforated loop by the formation of an anastomotic communication between the afferent and efferent limbs of the loop, will remove the annoyances incident to an intestinal fistula and place the parts in a more favorable condition for spontaneous healing or more successful surgical intervention. The anastomotic opening should be made at least two inches in length. The operation can be

performed most safely by the use of decalcified perforated bone plates or by Czerny-Lembert sutures.

ENTERECTOMY. The mortality attending enterectomy and circular enterorrhaphy in the treatment of intestinal fistula and artificial anus remains great even in the hands of experienced operators. The statistics of Reichel give a mortality of 37.8 per cent., and those of Hertzberg 27 per cent. In view of this fact it is apparent that this operation should be reserved for cases not amenable to successful treatment by safer procedures. I am confident that the indications for this operation can be limited to exceptional cases. If the intestine is not attached to the abdominal wall, it is much safer to open the free peritoneal cavity in search for the affected part of the intestine than to follow the fistulous tract as a guide. If possible, the intestine should be tied on each side of the fistula with a strip of gauze or a rubber band before it is detached, in order to guard more efficiently against fecal extravasation. The operation should be performed with the patient in the Trendelenburg position and the peritoneal cavity amply protected by aseptic compresses during the resection and suturing. After the resection the continuity of the bowel should be restored by circular enterorrhaphy by Czerny-Lembert sutures.

PRELIMINARY TRANSVERSE SUTURING OF THE INTESTINAL OPENING AS A PROPHYLACTIC MEASURE AGAINST INFECTION DURING THE OPERATION FOR ARTIFCIAL ANUS. There can be but little doubt that the operative treatment of intestinal fistula or artificial anus requiring opening of the abdominal cavity has been attended by an alarming mortality, owing to infection caused by the escape of feces through the intestinal opening. Packing the opening with gauze or cotton is a very inefficient way in which to prevent fecal extravasation. The use of clamps and ligatures on each side of the opening in the bowel is equally unreliable. It appears to me the only safeguard against this course of danger is preliminary closure of the intestinal opening by suturing, placing the sutures so close together as to absolutely prevent the escape of any of the intestinal contents. After this has been done the field of operation is once more thoroughly sterilized before the abdomen is opened and the intestine detached. The sutures should include all the tunics of the bowel. With few exceptions this row of sutures will remain as Czerny sutures, to be buried after the bowel has been detached by Lembert stitches. I have already made a statement that I look upon flexion of the bowel as the most important factor in producing the spur, and that measures which are calculated to correct the flexion will prove useful in removing the spur. In artificial anus, produced accidentally or intentionally, the flexion is caused by the prolapse of the intestinal loop into, and sometimes even beyond, the opening in the abdominal wall. If the intestine is detached the flexion is diminished or completely corrected, and its recurrence is prevented by transverse suturing of the intestinal opening. A study of my cases has convinced me that the provisional closure of the intestinal opening by transverse suturing before using the knife is the most efficient prophylactic measure against infection, and that resection of the intestine for fistula and artificial anus can be avoided in the majority of cases, and that in its place transverse suturing and correction of the flexion will yield better results.

TRIONAL.

CHARLES H. SPRINGER, M. D., PH. D., CLEVELAND, OHIO

I have used trional in a number of cases and found it, unlike any of the sedatives in common use, filling a place for which the pharmacopeia offers no other remedy. Having no anodyne properties, it is a hypnotic *par excellence.*

While opium acts by its benumbing influence upon pain, trional, where pain was absent or relieved by other remedies, relieves the nerve tension, quiets the "in a hurry" feeling, soothes the overwrought nervous system into a state or condition in

which natural sleeps follows, causing no nausea, dullness, derangement of the digestive organs, nor any skin eruption. The patient arises after from five to ten hours sleep with a ravenous appetite.

I do not remember reading of two noteworthy effects from the administration of trional:

First, on awakening, the patient does not have that longing for his morning drink, always noticed in other cases, and does not have that "hollow" feeling in the stomach; and, second, morphine or opium retards the action of trional. The patient in all cases has less tremors and no headache. I have never seen any unpleasant symptoms from the largest doses—grs. xxx. every hour until three doses were taken.

I usually administer the trional in capsules or "konseals." For simple insomnia, grs. xv., one hour before retiring, and the same amount on retiring, if necessary, is the usual quantity I prescribe. This method has given me the best results, and in twenty-one cases, with but one exception and that only for a night, the patients awoke much refreshed after sleeping from five to ten hours.

The following cases will show my plan of treatment and the results obtained:

Case 1. Insomnia, general nervous prostration and phosphaturia. Had not had two hours sleep at any time for more than a week. Trional in grs. xv., doses one hour before and on retiring and every hour until asleep, gave immediate relief. The first night three doses were given, which secured seven hours sleep; after this two doses each night secured from five to seven hours natural sleep, for one week. Since, the patient has taken only grs. xv. each night, and has not lost a single night's sleep in sixteen days.

Case 2. Insomnia, nervousness and enteralgia from an ulcerated colon. Ordered trional, grs. xv. with grs. v. each of phenacetine and acetanalid. The patient slept very well every night it was used.

Case 3. Insomnia, tremors and general nervousness or exhaustion from a protracted spree. Has been drinking large quantities of alcoholic liquors. Ordered grs. xv. trional every hour from 7 P. M. until asleep, and the following:

℞ Potassii bromidi ..... ʒ iii
Ext. cocæ Fluidi.. ..... f ʒ i
Celerinæ..... f ʒ ii

M. Sig.: Take one teaspoonful, in water, every hour tonight and every two hours tomorrow.

After nine hours sleep, he awoke tranquil in nerves and much refreshed, though weak. After a dose of the bromide he ate a hearty breakfast and by continuing the bromide and the acetanilid co. capsules, alternating every hour, had no longing for drink, no nausea, and was able to attend to business in the afternoon.

Case 4. Cocaine habitue having insomnia. Ordered grs. xv. of trional one hour before and upon retiring. This was the only remedy that successfully produced a refreshing sleep for him out of the many tried unsuccessfully.

I have used it as an anhydrotic with more satisfactory results than any other I have ever tried. I believe after a thorough trial that trional is a safe and reliable hypnotic and an anhydrotic of great value. It never causes any unpleasant symptoms, and for hypnotic and anodyne effect is best administered in conjunction with phenacetine or acetanilid.

THE CONTAGIOUS ASPECT OF PULMONARY TUBERCULOSIS.*

A. M. COOPER, M. D., Point Pleasant, Pa.

As there is so much being said and written about the contagious nature of pulmonary tuberculosis, I turned to my experience and observations for almost four decades to see if I could satisfy myself which side was tenable; I confess I was somewhat skeptical about the contagious nature of the disease before I investigated the matter and am more so now. However, my mind is open to conviction and change of opinion, whenever facts, sufficient, are presented to warrant the change.

The late Prof. J. K. Mitchell used to tell the class, that, where the consort was taken with consumption and died, the surviving partner was more likely to follow

* Read before the Medical Society of the State of Pennsylvania, 1894.

with the same disease than under any other circumstance in life. The intimate relation that existed between husband and wife, the well one was much more likely to become *infected* than under any other relation or condition. The word *contagion* was not thought of forty years ago in this connection.

I collected all the cases that I had attended, professionally, or who had come under my personal knowledge and observation and I found fifty-five such cases, when husband or wife had died of tuberculosis of the lungs with the following results to the remaining consort.

Fifteen husbands died of consumption of this number, and their wives are still living and well. Some have since remarried. One husband died about one year ago; one, three years ago, and the remaining thirteen from six to thirty years ago.

Of the above fifty-five cases, twenty-five wives died of consumption of the lungs and their husbands are alive and well now.

All these wives have been dead over six years, and some of them over thirty years.

Three husbands died of consumption and their wives lived many years thereafter, (one over thirty), and died of *old age* or some other disease.

Seven wives died of consumption and their husbands all lived to die of some other disease, and all died more than ten years after their wives.

Mr. M—— died April 17, 1870, of consumption, and his wife died of the same disease March 28, 1884. The wife following the husband fourteen years after his death from the same disease. Rather a long stage for incubation.

Mr. S—— died of consumption in the fall of 1872. Hsr husband afterwards remarried and died of the same disease in the spring of 1880—eight years later. The second wife has since remarried and is yet living and well. One case more which is peculiar.

Mr. and Mrs. B—— were married in 1871. She was not strong. He able to work, but coughing. She gave birth to twins August, 1872. The children lived a short time and both died, she never regaining her former health, but developed consumption in its rapid form and died in January, 1873. The husband died two or three years later from consumption, which had been of long standing. Mrs. B——, on her mother's side was from a consumptive family. As far as I know it did not exist in his family.

The last case is the only one in the fifty-five where there could have been any contagious influence exerted and that remains extremely doubtful. I am yet inclined to the opinion that heredity has more to do in the causation of pulmonary tuberculosis than anything else. I care not whether the germ of the disease is inherited or the productive soil, a fit and proper habitat for their implantation, development and multiplication, the fatal effects of the disease will be the same.

CORRESPONDENCE.

DR. LONGSDORF AND CHRISTIAN SCIENCE.

Mr. Editor:—In The Medical and Surgical Reporter for September 1, appears a criticism of Dr. Longsdorf's paper on "Christian Science," by Dr. J. Newton Hunsberger. While I most emphatically do not agree with the critic, yet I am glad in one sense that he wrote it and that The Reporter published it. Glad because the discussions of the papers read before the State Medical Society are never published, and these discussions, as in all medical societies, are often of as much value as the original papers. It would be of advantage many times if papers published in The Reporter, as well as in other medical journals, were taken up for "further remarks" by practitioners. It adds not only value, but interests one intensely in the subject, care being taken to remember that of all men doctors should be honest, fair and liberal.

In discussing Dr. Longsdorf's paper before the State Society, I took the ground that its valuable information would be of more importance in an educational sense to the laity, than to the profession. It is

evident, however, from Dr. H.'s criticism that some of the profession need to read it very carefully, more carefully, I am afraid, than the critic, Dr. Hunsberger has done. Had he "caught onto" the information given, and the real object of the paper, he would not have been so harsh and unkind as to call our good, womanly, gentle Dr. Longsdorf, "unjust, inhuman, selfish and cowardly." That is certainly not very professional, not to put it stronger. I can see her yet, standing timidly and modestly before the bald heads and gray beards, the middle aged conservatives and young enthusiasts that filled the old church on Walnut street, and I cannot possibly imagine any one of them yelling at her, "unjust, inhuman, selfish, cowardly," as she quietly finished. I am glad that in place of that, she received the cordial applause that she deserved.

Dr. Hunsberger accuses Dr. Longsdorf of facing both ways, in first "admitting that there were thousands of instances of authentic cures on record as a result of Christian Science," and then, "advising definite restraint" for "these abuses," and suggesting "legislative enactment." Now it happens that Dr. Longsdorf does not admit any such thing regarding "Christian Science," as above quoted. What she does say is this, "It would be out of place to argue against the possibility of *mental* cure." Then, she says, "*thousands of such instances are upon record*," etc. That is a very different statement than Dr. H. quotes, and has a very different meaning.

Prior to making the statement as to *mental* cures, Dr. L. carefully defined what "Christian Science" was by taking the definition *of its own leaders*. She clearly showed that taking *that definition*, "Christian Science" was a delusion, if not a veritable fraud. I think it is clear from her paper, that it (Christian Science) is a case of "the blind leading the blind," and both "falling into the ditch." It really looks as if our friend Dr. H. had slid in along with the rest. Dr. L says in effect the foundation is "belief," and the effect, if any, "mental," and in that way effecting the body physically. That is just the same old route by which the faith cure people, the Indian humbugged, the relic worshipers are effected. If one is *science* so are all.

Let me illustrate it from my point of view. When I was a young fellow, a patient that had been bedridden for years came into my charge. All the "old timers" in that section, had "tried, failed and given up the case." She was as a last resort turned over to the tender care and mercy of the "little doctor," as I was called. I did not know what was the matter with her. I have no doubt the "old timers" did, but they were very careful to not tell me. That woman would groan and moan for a period, and "lie awfully quiet" for another period; she had to be "hand fed" for days at a time, and was, as the head of the family put it, "the most awfullest helpless mortal critter that ever you seed." About that time clinical thermometers were coming into use and mine was a precious instrument to me. One night my patient insisted that she "was burning up," and that I must take her temperature. Taking my thermometer out of its flat case (it was one of those curved affairs fastened to a strip of wood or ivory), I approached the bed. Owing to some carelessness on my part the instrument fell to the floor and with a little bound passed under the bed. Full of anxiety for my new instrument, I grasped the lighted candle—candle seems odd at this day—and thrust it under the bed; it set fire to the "straw tick," and with a yell equal to a Comanche Indian the patient sprang to the floor and out of the room. The "cure" was permanent. Now mark the element of faith, for this old lady was no decendant of Ananias, that good woman declared most positively that it was the last dose of medicine that cured her; that she had only taken it half an hour before my arrival, and had "felt it going all through her body;" that "only for that dose she might have been seriously burnt." Mark again the element of credulity; the little doctor, at *that time*, was idiot enough to try and make himself believe that there really *was something* in her statement.

"Christian Science" (!) could have *cured* that patient.

Again, a woman had been bedridden for years; she was carried in a chair to a religious meeting of an excitable character. In the midst of the exercises the woman got up from her chair and walked across the floor. The "cure" was permanent. The result showed its perfect *naturalness*, as in the

previous case, by the fact of the patient "often giving out in the legs", until time and exercise had restored muscular tone.

"Christian Science" (!) could have cured that case. The fact in both cases being, that the patient could have walked at any time in all those years, *if they had believed that they could.*

Thousands of such cases have been "benefited," "cured," or "*changed their mind*," just as one may choose to designate it, by hundreds of different methods. None of them proof of a science evolved and made known.

If there is anything in its professions, then it applies just as well to a broken bone, a crushed limb, or an ovarian tumor as to a disease of any character that is *real.* These people are very careful to fight shy of that sort of thing, however. Did they confine themselves to cases that mental cures effect, it would not be so bad. But when they stand by the bedside of typhoid fever, diphtheria, scarletina, etc., etc., and talk about "belief," while the patient is fast hastening to the grave, denied intelligent assistance, *then* Dr. Longsdorf is right, and legislative enactment should be sought if nothing else will prevent the sacrifice.

Nor does the fact that they honestly believe in it help the case any. Nor yet does Dr. H. help the cause or his side by quoting, "If ye have faith like a grain of mustard seed ye can remove mountains," or by any appeal to the New Testament. The writer is a firm believer in the New Testament and the healing by the divine Christ, and by those whom He especially endowed. But if in these modern days the so-called Christian Scientists are to demonstrate the power "of faith like a grain of mustard seed," let them begin by feeding a few thousand of our worthy poor on "five loaves and two fishes." The lad with a basket and the needed material for beginning operations can readily be found. In this way they can do a great deal of good and no harm—that is if the theory works out right.

Again, before they begin experiments on the sick, let christian scientists ask and answer this question: "If the *mission* of Christ and His Apostles was that of healers of disease, was not that mission, as a mission, a failure?" If it was *not* the *mission* of Christ and His Apostles to cure disease, then any followers who so assume in His name, assume more than He or His Apostles did, and deceive themselves and others. All that Christ and His Apostles did in that line, was with a special object *above and beyond* the mere healing.

Dr. H. says further: "We are materialists. We look at our patients as mere machines. We forget that they are endowed with souls." Again is he much, very much mistaken. The great majority of physicians are believers in the Christian religion, even those who are not "professing Christians." The great hospitals, the wonderful research, the patient study, the anxiety, the care, the skill, the relief given by great surgeons and physicians as well as by us of the lesser ranks, to the suffering poor, without fee or reward, do not look as if our "patients were regarded as mere machines." Nor do the sacrifices of the profession for others indicate that we forget that we or they "are endowed with souls."

Again he says "we bow down and worship a lot of microbe resurrectionists, who were never in a sick room except that of dogs and guinea pigs, and have them dictate to us the quickest way to obtain a post-mortem." Let me say to Dr. H. that the above statement is not only "unjust—inhuman," but also a bad exhibition of ignorance. The class of doctors he seeks so to belittle have glorified the profession and blessed humanity.

The doctor quotes lastly, "There are more things in heaven and earth, Horatio, than are dreamed of in your philosophy." Let me kindly change it thus, "There are more things in the profession, Doctor, as well as in Dr. Longsdorf's paper than you have "caught onto."

Marienville, Pa.

The Endoscope in Urethral Stricture.

Dr. McMunn, in a recent article in the *British Medical Journal*, calls attention to the value of the endoscopic tube as a means of aiding the introduction of the filiform bougie in extreme cases of urethral stricture. Passing the tube down through the stricture, the aperture of the stricture is widened out by the stretching of the canal over the end of the tube, or brought into view by the change in the direction of the canal, so that the filiform instrument may be easily introduced.

Editor.

PENFIELD PUBLISHING COMPANY
Publishers.

Asbury Park, N. J.——1026 Arch Street, Philadelphia, Pa.

TERMS:—Three Dollars a year, strictly in advance. Sent four months on trial for $1.00.

REMITTANCES should be made payable only to the Publisher, and should be made by Postal Note, Money Order or Registered Letter.

NOTICE TO CONTRIBUTORS:—We are always glad to receive articles of value to the profession, and when used they will be paid for, or reprints supplied, as the author may elect. Where reprints are desired, writers are requested to make a note of that fact on the first page of the MS. It is well for contributors to enclose stamps for postage, that the articles may be returned if not found available.

SATURDAY, SEPTEMBER 22, 1894.

EDITORIAL.

A BACTERIAL STUDY OF ACUTE CEREBRAL AND CEREBRO-SPINAL LEPTO-MENINGITIS.

While the infectious nature of cerebral and cerebro-spinal lepto-meningitis has long been recognized, the character of the specific bacteria producing them has not been satisfactorily determined.

Biggs (*Wilder Quarter-Century Book*, 1893, p. 316) has recently contributed a valuable article on this subject from which important conclusions have been drawn. His studies were made on adult cases, and in the Springs of 1892 and 1893, during the eight weeks preceeding the first of May. It is during this period that vital statistics show the mortality from acute lobar pneumonia was highest (*i. e.* in the city of New York where these investigations were made); and it is to this disease that both cerebro- and spinal lepto-meningitis seems most closely allied in its etiology.

Of the eighteen cases studied by the author, six were cerebro-spinal, and twelve cerebral lepto-meningitis. In only three of the series was the disease secondary to traumatism, or to disease of the cranial bones or of the soft parts about the head. Of the cerebral cases, one was primary and eleven secondary to some local or general acute infectious process. A bacteriological examination was made in seventeen of the cases. In the twelve cases of acute cerebral lepto-meningitis the bacterial examinations gave the following results:

In one case, pure cultures of the *Anthrax bacillus.*

In one case, *Bacillus coli communis.*

In one case, *B. coli communis and Proteus Vulgaris.*

In four cases, the *Pneumo-bacillus of* Fraenkel.

In two cases, the *Streptococcus pyogenes.*

In one case, the *Diplococcus intracellularis meningitidis.*

In two cases, a mixed infection.

The finding of the localization of the *Anthrax bacilli* in the brain, is of particular interest. The patient was a wool-sorter, thirty-six years of age. He died in eighteen hours after the first symptoms of the cerebral trouble. Upon post-mortem, "the *pia mater* of the brain over both the convexity and the base was studded with hemorrhages, and the meshes of the *pia*

both in the fissures and over the convolutions were distended with sero-pus. Cultures were made from the fluid in the subcutaneous tissue from various portions of the wrist and arm (seat of inoculation), from the heart, blood, spleen, and *pial* exudate on both sides of the brain. In all of the tubes inoculated from the brain, a pure culture of the *Anthrax bacillus* developed. All of the other tubes remained sterile. The media employed and the conditions under which the cultures were made and kept after inoculation, were the same. The identity of the *Anthrax bacillus* was established by microscopical examination, by culture reaction and by inoculation of animals." Cover-glass preparations from the various organs also failed to reveal the presence of the bacilli, excepting in those from the brain.

The appearance of *Bacillus coli communis* in pure culture in the brain, is also interesting as it furnishes another evidence of the distribution of that organism in the body. It is believed by the author that this bacillus was the exciting cause of the meningitis, as it appeared in pure culture and followed after typhoid fever. The explanation being the migration of the colon bacteria through the intestinal ulcers into the blood or lymph channels, and eventually lodging in the meninges, where they set up an acute inflammation.

The *Pneumo-bacillus* of Fraenkel was found in four cases where the meningitis followed lobar pneumonia. The presence of this bacillus in acute meningitis has been known for some time, and certain writers have been led to the opinion that this bacillus is nearly always the etiological factor in this disease. The results of the author show, however, that other agencies are quite abundant.

An observation of much interest is added by the writer, that he has rarely seen cases of cerebro-spinal meningitis at any other season of the year than during the spring months, and these cases are almost invariably primary and develop suddenly without any ascertainable cause.

The following important statements are made by the author:

1. "Purulent or sero-purulent meningitis is always microbic in its origin.

2. "Many cases of cerebro-spinal meningitis do not differ from cerebral meningitis except in the extent of *pia* affected. The etiological factor may be the same.

3. "Cerebro-spinal meningitis is usually primary.

4. "Cerebral meningitis is usually secondary to some infectious disease and is only occasionally primary.

5. "When the disease is secondary, the cause of the secondary infection may be a different organism from that producing the primary disease.

6. "The following organisms have been previously found in the *pial* exudate in cerebral meningitis: The *Pneumo-bacillus* of Fraenkel, the *Streptococcus pyogenes*, *Bacillus Typhosus*, *Staphylococcus pyogenes*, *Pneumo-bacillus* of Friedlander, the bacillus of '*La Grippe*' and the *Gonococcus*." The authors' observations have added two new ones, *Bacillus Anthracis* and *Bacillus coli communis*.

7. "The *Pneumo-bacillus* of Fraenkel is the most frequent cause of cerebral meningitis.

8. "The latter organism is not infrequent cause of primary cerebral and cerebro-spinal meningitis, the lungs not being involved.

9. "The cases of meningitis due to different organisms do not show such constant differences from each other in the symptoms presented, as to make possible the clinical differentiation as to cause.

10. "The amount of exudation bears no constant relation to the severity of the symptoms.

11. "It is not possible to distinguish with certainty during life, cases of acute cerebral hyperæmia, with or without œdema, from cases of meningitis."

ABSTRACTS.

REVIVAL OF SYMPHYSEOTOMY.

The literature of this subject has in recent years become so voluminous that it would be impossible to find space to do more than summarize the accounts of the most striking work done in Italy, France and Germany, where the operation has been most frequently performed, and has found the most prominent supporters.

Historical.—The operation was first proposed by Sigault, of Dijon, in 1768, and first performed at Naples by Domenico Ferrara in 1774. Ever since then there have been champions of the operation in Naples,* notably Amantea and Galbiati, and in more recent times Spinelli, Caruso and Morisani. The last of these called attention to his operative work for the first time in 1863, and his contribution of facts and opinions on symphyseotomy was perhaps the most remarkable feature of the Gynecological Section's Proceedings at the recent Congress at Rome. Throughout the rest of Europe the operation was entirely abandoned as too dangerous. This result was largely owing to the discussion which took place between Sigault and Baudelocque. In this discussion Baudelocque appeared to bring forward unanswerable arguments drawn from his experiments upon the cadaver, especially proving the absence of increase in the conjugata vera and the occurrence of fraction of the sacro-iliac joints as results of the operation; and though his conclusions were shown later to be erroneous, they were accepted at the time. It was not until great advances had been made towards exact pelvimetry, and antiseptics had been introduced into obstetric surgery, that the results obtained by the Italians were sufficiently encouraging to attract favorable attention in France and Germany, and, curiously enough, it was at the Clinique Baudelocque in Paris, that the most strenuous advocates of symphyseotomy were found.

Symphyseotomy in Germany. — The transactions of the German Gynecological Society at its meeting at Breslau in May, 1893, will perhaps best serve as the basis of a review of the German material up to that date.

Zweifel, of Leipzig, gave an account of his experience, referring to previous papers of his own and of others on the same subject, and frankly admitting that his opinion on the subject had undergone a complete change. He mentioned fourteen cases of symphyseotomy occurring in his clinic. All the fourteen women recovered completely, without any unfitness for exertion. Two of the children were stillborn, or died immediately after birth. He found it impracticable to follow the example of the Neapolitan school, and wait for spontaneous delivery after the cutting portion of the operation. He had to apply the forceps in ten of the cases, but always with the head low in the pelvis. The weakening of the fœtal heart-sounds was in every case the indication for the use of the forceps; and in six of the cases coiling of the cord round the neck of the fœtus was found to be the explanation of the indications.

As to the *technique* of the operation, Zweifel calls attention to the following details. The incision through the skin gives rise to smart hemorrhage, which can be readily stopped. The introduction of the finger behind the symphysis and the protection of the knife in cutting through the cartilage from above downwards are easily effected. Only in one case had he to use the chain-saw, owing to difficulty in completing the incision through the symphisis. Difficulties may arise here, not from ossification, but from obliquity in the direction of the symphisis or irregularity in the form of the pubic bones. When the cartilage is cut through the pubic bones separate about a quarter of an inch, and when the last fibres of the ligamentum arcuatum give way, the distance between the bones amounts to a finger's breadth. Then comes on very considerable hemorrhage, which is very difficult to stop. It is best arrested by the introduction of a tampon with counter-pressure from the vagina. When this has been done the patient may be put back to bed and labor allowed to proceed

* Corradi. "History of Obstetrics in Italy during the 18th century."

for twelve or fourteen hours. In many cases the os is not fully dilated, although the membranes may have ruptured at the time of the incision. When the head is passing through the narrow portion of the pelvis the pubic bones sometimes separate to the extent of 2½ to 2¾ inches. In such cases there is always fresh hemorrhage and the need for additional *tamponnade* to arrest it.

After the completion of parturition, another set of circumstances demand attention. Zweifel says that the old accouchers used to fix a cerviette round the pelvis, and healing took place. He himself had to resort to suture of the bones in eleven cases. He describes the difficulties in the way. He used silver wire and it cut through; he separated the periosteum with a raspatory, and took a larger hold of the bone; and he finally succeeded in bringing the separated surfaces of the symphysis together. He says this proceeding is not difficult, but recommends that it should not be attempted in private practice. It may be sufficient to follow the Italian method of suturing the fascia, and so turning in the feet when the legs are extended as to diminish dragging upon the symphysis. In order to keep the pelvis still and immovable, a special girdle was used at first, but in later cases strips of plaster fixed round the pelvis were found to be as efficient and more comfortable. In three cases in which silver wire was used incontinence of urine came on, and required treatment later. In Sweifel's cases the ability to walk soon returned. There was a slight increase in every case in the transverse diameter of the pelvis.

The puerperium was favorable throughout in only three of the cases, and five of the number were ill, with high temperature, for a long time.

Attention is called to the extensive lacerations of the maternal soft parts, which may be as serious as the injuries to the sacro-iliac joint. Such lacerations occurred in Zweifel's cases once spontaneously, and three times during forceps delivery. Three of the women were primiparæ. Later experience has led many operators to the conclusion that symphyseotomy should not be performed upon any woman during her first labour.

At the same congress Döderlein, also of Leipsig, described and illustrated his observations on certain questions bearing on the operation. He set himself, first, to answer the question, What is the condition of the sacro-iliac synchondrosis when the pubic bones are separated during the operation? The second question to be answered was, Is the amount of room in the pelvis gained by the operation a sufficient advantage to place against the dangers and difficulties of the operation? On the first head he found, contrary to the accepted traditional views of Baudelocque, that in the pregnant woman at full term the sacro-iliac joint does not fracture; there is only a partial tearing of the capsule of the joint and especially of the anterior sacro-iliac. ligament. "The joint is opened and the fluid in the joint escapes; if small vessels are torn there may even be an extravazation of blood into the joint. As soon, however, as the pelvis is restored to its proper shape on the completion of labour the injuries are quickly and completely healed if no infection has occurred." On the question of increased space in the pelvis Döderlein proved by experiment that when the pubic bones were separated six centimetres there was an increase in the inlet equivalent to 50 square centimetres, and when the symphysis was separated eight centimetres there was an increased area of the inlet equivalent to 66 square centimetres.

Leopold, of Dresden, had performed the operation four times. He thought it was not an operation for general practice, and was not likely to become so. The upper limit for the conjugata vera is 8cm. (3⅛in.,) and the lower limit 6cm. (2⅜in.) Labour should be allowed to proceed until the os is completely dilated, and then the whole process should be completed at once by the application of the forceps. The greatest possible care must be exercised to prevent laceration of the vagina. Primiparæ should never be subjected to the operation.

The discussion was continued by Chrobak and Schauta, of Vienna; Olshausen, of Berlin; Fehling, of Basel; and others who had done the operation very seldom or not at all. It brought out differences of opinion on various points, such as the relative danger of injuries to the bones and to the soft parts, the need for suture of the bony parts (Knochen-nacht), the relative frequency of pyrexia and symptoms of sepsis after operation, and to what extent symphyseotomy would do away

with the necessity for perforation of the living fœtus.

Such was the state of information and opinion among German obstetricians little more than a year ago.

In the discussion on symphyseotomy, which took place at the International Medical Congress in March last, Leopold and Zweifel among others took part, and the former said that it was his duty to explain the position in the controversy occupied by German obstetricians. He and his colleague, however, brought out the fact that they had not in any way changed their views on controverted points. Leopold still spoke in favor of premature labour practised not earlier than the 34th week, and Zweifel advocated, as formerly, delay after the cutting portion of the operation, so as to avoid the application of the forceps. His cases had now increased to 23, all the mothers were alive, and 21 of the children. There had been no incontinence of urine, no fistula, no serious puerperal affection, but in three of the women walking continued for a long time to be difficult.

Sänger, of Leipzig, joined in the discussion to compare the operation with Cæsarean section. He said his mortality for 12 cases was nil. In general the mortality of the two operations differs little. If we compare the time occupied by the two operations, we find that Cæsarean section takes about an hour, and requires no after treatment, whereas symphyseotomy, according to Zweifel's method, demands about a day, and the after treatment continues for about a year. Symphyseotomy in Sänger's opinion ought to be more limited in its scope, and that of the Cæsarean operation extended.

Symphyseotomy in France.—The revival of symphyseotomy in France chiefly depends upon the clinical work of Pinard. This clinical work is explained and justified by the anatomical and experimental studies of Professor Farabeuf* and of Dr. Varnier.

Up to the time of delivering his address on symphyseotomy at Rome in March last Pinard had performed the operation 36 times, with the result that two mothers and four children died. No accident had occurred in any case during the incision of the symphysis and enlargement of the pelvis. Hemorrhage had always been stopped by using a sponge as tampon. During the extraction of the fœtus in primiparæ laceration of the anterior vaginal wall occurred five times. The tears were not extensive, and gave rise to little trouble. The practice of preliminary dilatation by means of Champetier's bag rendered laceration a rare occurrence. Incontinence of urine continued for a considerable time in one case. In all the cases consolidation of pelvis was complete by about the twentieth day. The after-history, in a considerable number of the cases, showed that the women were engaged at laborious occupations, and did not suffer in any way. One of the women became pregnant about three months after undergoing the operation, and went through normal spontaneous parturition at full term in the *clinique*.

Pinard gives a table showing a comparison between the results obtained in cases of contracted pelvis by the induction of premature labour and by symphyseotmy. In sixty-four cases of the former two mothers and thirty children were lost, whereas in thirty-six of the latter two mothers and four children were lost. The author proceeds to give a *résumé* of the anatomical and experimental researches of Farnbeuf. He begins with the remark, "Ces notions anatomiques sont ennuyeuses." With this opinion most readers will agree. The summary itself is long, and incapable of further condensation. Pinard then gives a carefully detailed illustrated account of his method of operating. He "indicates the method by which the difficulties and dangers of the operative proceedings are to be suppressed."

He finally formulates his conclusions as follows:

1. Symphyseotomy or pubiotomy performed antiseptically is not a dangerous operation.

2. In order to be useful it ought to be complete, and the preliminary separation of the pubic bones ought to be in proportion to the contraction of the pelvis.

3. The operation should be performed only on those cases in which examination and measurement of the pelvis show that separation of the pubic bones to the extent of 2¾ inches will permit the passage of the fœtal head at term.

* "Possibilite et moyens de traiter scientifiquement la dystocie du detroit superieur retreci."—*Annales de Gynecologie*, May-June, 1894.

4. Separation of the pubic bones exceeding 2¾ inches, being capable of producing lesions of the soft parts, should be proscribed.

5. When the contraction of the pelvis is such that separation of the pubic bones to the extent of 2¾ inches will not permit of the passage of the head of the fœtus, recourse should be had to Cæsarean section (Porro's operation.)

6. In case of oblique ovular pelvis, with synostosis of one of the sacro-iliac articulations, when the contraction does not permit of spontaneous delivery, it is best to perform the operation of Farabeuf, that is, ischio-pubiotomy.

He adds the following "general conclusions":

1. Embryotomy, cephalotripsy, and waiting for the death of the fœtus ought to be forever proscribed.

2. Operative enlargement of the pelvis, conducted according to the rules laid down, ought to lead to the abandonment of (*a*) the induction of premature labor; and (*b*) every operative proceeding having for its object to make the fœtal head struggle against osseous resistance which cannot be overcome by the uterine contractions.

Symphyseotomy in Italy.—The work of the German and French obstetricians in symphyseotomy is a mere reflection of that done in Italy, and more especially of the work of Morisani, of Naples. Morisani's first publication, "On the contraction of the pelvis and the indications which appear at the time of parturition," attracted considerable attention to symphyseotomy. It appeared in 1863, and since then numerous papers have conveyed to the medical profession a knowledge of his clinical work and of his opinions. He has also been aided in his advocacy by able colleagues and disciples, who have been active clinical workers and diligent contributors to the literature of the subject. One of the most useful of these contributions was that of Spinelli, "Sulla Sinfisiotomia, annotazioni storiche, critiche e bibliografiche," which ran through several numbers of the *Annali di Ostetricia e Ginecologia* in 1892. Among the numerous addresses and papers of Morisani, one of the most important was a contribution to the same journal in January, 1893, "Per la Sinfisiotomia," in which he gave the statistics and details of fifty-five cases. And now quite recently, at the International Congress, his address on symphyseotomy placed before the profession his most mature experience and reflections.

Symphyseotomy is now rendered a justifiable operation by our clinical experience. We are enabled by it to extract a well-developed child at term through a contracted pelvis with a conjugate diameter of 6-7 cm. to 8-8 cm. (2⅜in. to 3½in.) The operation is contra-indicated when the fœtus is dead, or even very feeble. The time for operation is when the pains are in full force and the dilatation of the os is well advanced. If it be objected that with an antero-posterior diameter of 3⅜ in. spontaneous birth is possible, or the forceps may readily complete the parturition, it may be answered that a favorable termination is only exceptional, and that the use of the forceps in such circumstances is "masked cephalotripsy," with this difference, that the ordinary cephalotribe would produce less grave and dangerous injuries to the maternal parts. This conviction, however, should not lead to rash action; in every doubtful case plenty of time should be allowed to the natural forces, and the forceps even may be cautiously tried before resorting to symphyseotomy.

In the employment of version in cases of modern contraction, Morisani has no confidence. The mortality among the children is enormous; Zweifel puts it at 29 per cent.

Two or three combinations of other operations with symphyseotomy are discussed: The combination with induction of premature labour is rejected; the combination with embryotomy in certain rare cases is considered advantageous.

The operative details are easy of execution, and do not involve any danger to the patient worth mentioning. The curved bistoury of Galbiati is not essential. Any knife with a protected point and a narrow, strong blade will do. Morisani has never met with ossification of the symphysis, but admits that a chain saw may be required when there is great obliquity and irregularity of the symphysis. It is essential that the accoucher ascertain that the subpubic ligament is completely divided, and that all the structures of the joint are so cut as not to interfere with the separation of the surfaces. When the thighs are abducted, the separation should extend at once to 4 or 5 cm., and in some

cases even to 6 or 7 cm. As soon as this preparation has taken place Morisani applies the forceps and completes the labour. He justifies this course as against Zweifel's advocacy of delay. When the labour is over the wound is at once closed with silk sutures, which are applied as both deep and superficial. Osseous suture is shown by Morisani's statistics to be unnecessary. He has also given up special appliances for holding the pelvis immoveable. Simple bandaging and tying the knees together suffice for obtaining a perfect cure.

Hemorrhage has never been a troublesome feature in Morisani's operation. *Tamponnement* of the wound has always been sufficient to arrest it. The lacerations of the anterior vaginal wall, spoken of by some, have figured little in the practice of the operators at Naples. They might be altogether avoided if primparæ were not operated on, and if the innominate bones were pushed together towards the end of the extraction so as to support the soft parts.

In comparing symphyseotomy with other operations, Morisani thinks that it does not come into competition with Cæsarean section, inasmuch as one begins where the other leaves off. With a conjugate diameter of less than 6.7 cm., the Cæsarean operation "conserves its rights." He deprecates the resort to abdominal section, with its mortality of 12 per cent. in cases where symphyseotomy should give a favorable result.

As to craniotomy on the living child, the maternal mortality is appreciable, and the balance of advantage lies with symphyseotomy. As to the advantages of induction of premature labour, Morisani has changed his mind. If the deformity of the pelvis be such as to require for the birth of a living child induction at the end of the seventh month, or in the course of the eighth, then symphyseotomy should be resorted to. The results of induction so early are "deplorable." "The great majority of the children die," in spite of all the appliances to keep them alive.

The statistics of symphyseotomy appear to require careful handling. The number of cases collected from various sources is 241, showing a maternal mortality of 11.6 per cent. Some of the deaths were due to causes unconnected with the operation. The result of the 241 operations, as far as the fœtus was concerned, was 186 living children and 55 deaths. Of these deaths it is sought to explain away 25.

Morisani's own results, as published in January, 1893, in the paper already referred to, show 55 cases in the five years from March, 1887, with two mothers and five children lost, a very remarkable maternal mortality for such an operation.

Morisani's final summary does not contain any fresh point, except, perhaps, his insistence upon the disastrous results of operating upon women with pelves contracted beyond the minimum of 6.7 cm. of conjugate diameter.—Sinclair, in *Med. Chronicle*.

Scarlet Fever from Milk.

Dr. Chalmers, of Glasgow, recently reported an outbreak of scarlet fever which was traced to a dairy, one of the milk boys of which had suffered from the disease. It was not proven that the cows had suffered any malady to which scarlet fever could be traced.

Management of the Intestine After Abdominal Section.

Drs. Skene Keith and George E Keith (*New York Journal of Gynecology and Obstetrics*) say:

When the general condition of the patient is fairly good and the abdomen is not distending, and when there is not much colic, let things take their natural course. This advice holds for the great majority of cases.

When the abdomen is distending without a previous state of peristaltic action shown by much colic, and when there is a tendency to vomiting, give the mixture of magnesia until the bowels move.

Treat distention without colic or vomiting by the quinine injections.

Quiet excessive peristaltic action by small doses of morphine given hypodermatically.

For distention following excessive peristalsis give a small dose of morphine followed in a few hours by castor oil or magnesia.

When there is septicæmia, wash out the abdomen as soon as the condition is evident and treat as above.

Do not get into the habit of calling septicæmia shock, exhaustion, or any such term. Be content to believe that some mistake has been make in the antiseptic precautions and that additional care must be taken in future.

CURRENT LITERATURE REVIEWED.

IN CHARGE OF ELLISTON J. MORRIS, M. D., AND SAMUEL M. WILSON, M. D.

ARCHIVES OF PEDIATRICS,

for August. Dr. F. Huber discusses

Congenital Constipation.

He comments upon the slight importance parents give to constipation in infants. When they pay any attention to the subject they give any remedy that they think suited to the case. In addition to the well-known causes—improper feeding, poor quality of milk, faulty intestinal innervation, etc., the author thinks the peculiar arrangement of the colon a direct and rarely recognized cause. The length of the large intestine is comparatively greater in young children than in older ones or in adults, and to accommodate this it must fold back, sometimes several times, on itself, thereby effectually preventing the passage of feces.

When this condition exists and leads to obstruction, the child becomes quite ill, suffers pain, has a terse abdomen, and careful examination is necessary to diagnose properly.

To relieve the condition it is best to use a copious injection, gently administered by a fountain syringe elevated a very little, but it is often necessary to introduce the pipe some distance into the bowel. It may be found necessary to raise the bag to some height, and also to use calomel, oatmeal water, etc. In any case it is necessary to continue the high rectal injections for some time, and to keep the case under constant observation for years.

In the discussion which followed, one of the members taking part seemed to advocate the use of ox-gall. sweet oil, or turpentine, but had not used these remedies continuously in cases.

Dr. Chayles W. Townsend writes of

Hæmorrhagic Diseases of the Newborn,

The author thinks his experience proves the existence of a contagious disease, not dependent in any way on puerperal septicæmia, and causing in infants, usually of two or three days of age, (almost always under seven) hemorrhages from mucous surfaces. This disease he thinks quite distinct from hemophilia, self limited, and when leading to umbilical hemorrhage, invariably leading also to hemorrhage elsewhere.

He proposes a supportive treatment, bathing, etc., and frequently finds it necessary to feed breast milk from a spoon instead of depending on the baby nursing.

In collapse external heat and alcoholic stimulants are useful. Astringents and mineral acids seem worthless.

Dr. John Lovett Morse reports

Five Cases of Gonorrhœa in Little Girls.

These children ranged in age from two years to five and three-quarters. The symptoms were inflammation of the external genitals, more or less discharge, usually painful micturition. Each case showed the presence of gonococci, and no non-specific cases were met with by the author; so that he concludes that valvo-vaginitis in children of this age is usually specific. There was no suspicion of rape in any case, and no satisfactory cause could be assigned except the probable use of bath tubs and towels in common with infected adults.

Dr. B. K. Rachford discusses "The Influence of Venous Congestion on Spinal Reflex Centres." Dr. Francis Huber reports a case of "Congenital Hypertrophy of the Fingers." Dr. Henry Dwight Chapin writes about the "Symptoms of Intestinal Obstruction Without Stenosis." Dr. Irving M. Snow reports a case of "Purpura Hemorrhagica Complicating Lobar Pneumonia." Dr. Charles A. Leale describes a rare case of Tuberculosis and Sarcoma.

ARCHIVES OF PEDIATRICS.

Dr. J. Henry Fruitwright continues his article on

Infantile Scurvy.

The case of a boy nine years old is described; he had lived for some time on salt meat, dry rye bread and black coffee, and complained of what his mother called "growing pains." This boy had oval swellings about the knee, very sensitive to pressure, ecchymoses on the chest and elsewhere, foul breath, alternate constipation and diarrhœa, and began improving as soon as given antiscorbutic diet and treatment.

The author describes the treatment of the disease as follows: The joints of the lower extremity take on an unnatural immobility, resembling a pseudo paralysis, and accompanied by tumefaction and exquisite pain on pressure.

The radius may be affected, but the most characteristic bone symptoms are the cylindrical swelling of the lower ends of the femur and tibia. The skin covering the swellings is tense, shiny, pale, without local heat, and will not pit on pressure. There is great liability to fracture of the bones near the epiphyses. Fever is not constant. In neglected cases profound anæmia supervenes, subdermal ecchymoses form, and ulceration may result; also epistaxis, enterrhagia, hæmaturia, etc. "Hemorrhages are most common where epiphyseal growth is active," and may occur under the periosteum anywhere, leaving a cast to be found post-mortem.

Scurvy is most commonly mistaken for acute rheumatism, but differs from it in the shape of the swellings. In scurvy these are cylindrical or fusiform, and in rheumatism they are more apt to be lateral or circumferential, with local rise of temperature, and

with local points of tenderness on pressure. In scurvy the swelling is uniformly tender, and white and tense.

Rheumatic purpura might complicate the diagnosis, and if mouth symptoms be absent the therapeutic test might have to be relied on.

It may be necessary to rely on the therapeutic test in cases simulating Pott's disease, etc., but in cases of long standing the symptoms of scurvy should be too well marked to make this at all needful.

Two varieties of purpura somewhat resemble scurvy. In peliosis rheumatica the peculiar joint symptoms of scurvy do not precede the eruption, although pain is a prominent symptom in it.

Purpura hæmorrhagica simplex was once thought identical with scurvy, but the diagnosis lies in the absence of pain around the joints.

In treating scurvy the author relies almost wholly on the diet, excludes all artificial foods, and gives sterilized or pasteurized cows' milk, and, if the child be old enough, fresh scraped beef and baked or mashed potato The juices of the orange, lemon, lime, and apple are very useful. Iron, or the citrate of iron and ammonia are useful to combat the effects of this disease, ergot may be necessary if there be much hemorrhage from the mucous membranes, and other remedies may be required if individual symptoms are marked.

BRITISH JOURNAL OF DERMATOLOGY FOR AUGUST.

Dr. Alfred G. Francis writes of

Elephantiasis Associated With Tertiany Syphilis.

Cases are reported at some length. In one case where, as in the others, the history and scars of syphilis were easily found lymphatic abscesses and then lymphorrhagia occurred a few weeks before death.

In the majority of cases the disease is limited to one limb, and this has usually been the seat of syphilitic ulcers, etc. The enlargement is much less marked than in cases of filarial origin or lymphoid disease, and at intervals becomes the seat of inflammation limited to the affected part, leaving it larger than before. These attacks of inflammation are called elephantoid fever.

The resemblance which these cases bear to the milder varieties of tropical elephantiasis leads to the suggestion that these also are caused by lymphatic obstruction. Although there were no other symptoms it is probable that in the case of lymphorrhagia referred to the abscesses had pierced some varicose lymphatics. No nerve lesion was found in any case so that a trophoneurosis is excluded from consideration.

Syphilis causes elephantiasis frequently, and that when confined to the genitals the enlargement is not entirely due to gonorrhœal secretions is proved by its appearing in males, where the discharge can be proved absent. The author regards the well known connective tissue hypertrophies of internal organs an analogous affection.

Dr. Stephen Mackenzie reported a case where a "papulo tubercular, squamous, and crustaceous syphilide" was partly distributed along a nerve, resembling in this herpes zoster.

THE ANNALS OF GYNÆCOLOGY AND PÆDIATRY

for August. Dr. Henry Parker Newman contributes a paper on

Shortening the Round Ligaments for Uterine Displacements,

giving the results of six years experience with the procedure. The author meets the objections usually urged against the operation, namely, the difficulty of finding the round ligaments, the possibility of breaking them and their absence. His answer to the first is that by his method of cutting down on the inguinal canal directly over the internal ring it is always possible to find the ligament and the danger of breaking it is much less than by the old method of searching with for it among its divergent filaments. He denies that the liagments are ever absent and also asserts that from experiments on the cadaver he is convinced that they will stand a much greater weight than is likely to be imposed on them by the uterus. His method of operating is as follows: An incision is made an inch and a half or more in length, parallel with Poupart's ligament, directly over the canal of Nuck, which is midway between the spine of the pubis and the anterior superior spinous process of the ilium. This initial step exposes the glistening aponeurosis of the transversalis muscle. Through a single nick in the course of the separated fibres of an aponeurosis the blunt hook may now be passed into the canal and the round ligament, which will be seen as a whitish, slightly flattened, cork-like structure, pulled out. Where the operator is not confident of his ground the author suggests the lengthening of the incision to confirm the identity of the ligament. Or an assistant can draw the uterus backward by a sound or finger, when the tension on the ligament will be seen and felt in the wound. After the ligament on one side is secured the opposite side is also found and the both ligaments are drawn upon, exposing in the canal of Nuck a reflection of the peritoneum surrounding the ligaments like a glove finger. This should be stripped back until the ligament can be drawn well out and the uterus sharply anterverted. This gives a loop of ligament on either side, about four inches in length, to be disposed of by stitching the proximal ends together, and anchoring them firmly to the aponeurosis and walls of the canal by buried sutures, care being exercised to avoid strangulation or disturbance of its nutrition. The wound is closed with one series of silk-worm sutures made to include the walls of the canal, the aponeurosis of the external oblique, and the superficial coverings. Patients are kept in bed three

weeks or more. until firm union of the incised structures has taken place, and precautions against over-exertion or straining of the parts are insisted upon for as many months. Hernia is guarded against by the deep sutures constricting the canal about the internal ring, insuring firm union where most needed. Appended to the paper is the report of a number of cases.

Dr. E. E. Montgomery discusses

Vaginal Hysterectomy,

giving as the indications for the operation the presence of malignant disease, the presence of a number of fibroids in the uterine walls where the hemorrhage is so great as to endanger life, and also procidentia uteri accompanied with ulceration of the vaginal surfaces. He suggests that in the after-treatment, so soon as the patient recovers from the shock of the operation, the upper part of her body be elevated slightly, in order that drainage be favored. The author favors the use of the clamp in preference to the ligature for securing the broad ligaments. "The advantages of the use of the clamp over the ligature have seemed to be the greater rapidity with which the operation can be performed; second, the greater security against hemorrhage; third, the more effective drainage, due to the pressure of the clamp upon the perineum and vagina; fourth, the absence of any foreign body to delay union as a result of infection. After a careful study of the cases which have come under his observation, the writer fails to see wherein there are any contraindications to the use of the clamp that are not more than compensated by the advantages already cited."

Dr. George Tucker Harrison discusses

Hæmatocele Retro-uterina.

The author thinks that the term hæmatocele or, more specifically in its typical form, hæmatocele retro uterina, should be limited to an effusion of blood into Douglas's space, previously shut off from the general peritoneal cavity by pseudo membranes, the result of a previous pelvio-peritonitis, forming a tense tumor which displaces the uterus forward. It should be carefully discriminated from a free effusion of blood into the peritoneal cavity, on the one hand, and an effusion of blood into the connective tissue of the pelvis, constituting an hæmatoma, on the other."

In regard to treatment, he states that he is unable to see the advantage accruing from laparotomy, as the operation adds to the dangers and a necessary accompaniment is drainage through the bottom of Douglas's pouch. He rather would make broad transverse incision at the deepest place of the posterior fornix vaginæ, and then, by blunt scissors, clear the way to the sac. If there is a plain sac-wall, it is sutured above and below to the walls of the vagina. The blood coagula are now removed by the fingers without the use of force. If there is any bleeding, the use of iodoform gauze is indicated. If not, a rubber drainage tube, with the addition of careful irrigation is in place.

Dr. Walter A. Crow contributes a short paper on

Cancer of the Uterus.

Considering the remote results of operative interference, the author quotes the opinions of various authorities and reports a number of successful cases—successful so far as recovery from the operation is concerned but in some instances the disease returned and in others the time since operation is to short to make the cases of any value. He takes the view that cancer in the beginning, as a disease, is purely local and urges on the profession the need of early diagnosis and operative interference.

The remaining papers in this issue are: "Ultimate Results in the Treatment of Backward Displacements of the Uterus," by Pessary, with Especial Reference to the Alexander-Adams Operation, by F. H. Davenport, M. D., published in *The Ameaican Journal of Obstetrics* for July, and reviewed in THE MEDICAL AND SURGICAL REPORTER for September 1st, page 309. "Rupture of the Uterus; Palliative versus Surgical Treatment," by Charles M. Green, M. D., published by *The American Journal of Obstetrics* for July and review in THE MEDICAL AND SURGICAL REPORTER for September 1st, page 308. "Inflammation of the Ureters in the Female," by Mathew D. Mann, M. D., published in *The American Journal of the Medical Scienees* for August, and reviewed in THE MEDICAL AND SURGICAL REPORTER for September 8th, page 341.

THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES

for September.

Two papers appear in this issue on the subject of Leprosy. The first is by Dr. James Nevins Hyde entitled

The Distribution of Leprosy in North America.

The author does not include syringomyelia, Morvan's disease, scleroderma, morphœa, Raynaud's disease, or ainhum as among the manifestations of leprosy, as he thinks there is not yet sufficient evidence to establish these as forms of the malady. He is also of the opinion that the tubercular, anæsthetic, macular, mutilating, and mixed forms of lepra should figure no longer in the statistics of the disease. They are not varieties, but different external expressions of one and the same malady, often simultaneously shown in the same patient. From the data at his command he computes that there are ninety-two lepers now alive in this country. "There are actually two lepers in Florida; and usually from one to three in Illinois, and the same number in New York. One is known to be in Texas, two in Idaho, two in Pennsylvania, four in South Carolina. There are probably more than threescore of lepers in Louisiana, and less than half that number in the States of the Northwest. This suggests an approximate estimate of between one hundred and two hundred cases of lepro y. Competent

observers have estimated that the total number is between ninety and one hundred and fifty. It can scarcely be doubted that in each of the last fifteen years there have rarely been fewer than one hundred lepers living within the territorial borders of our country." The author cites an instance of a leper twice making the journey from Chicago to Sweeden and finally dying in Chicago.

"These figures," he says, "are not to be reviewed either with the hysterical alarm of the timid or with the careless indifference of the unwary. They call for intelligent discussion and for a wise provision, alike for the need of the unfortunate leper and for the safety of the community in which the infected are now living. There are greater problems presented to the physicians of America than those growing out of these interesting statistics. Tuberculosis alone exposes at present, to a greater danger than lepra, the health of our population. But enough lepers are now sheltered upon this soil to offer a menace to the welfare of its inhabitants and to propose a problem in State and sanitary scientific which I believe the General Government alone can rightly solve."

The second paper on the subject is

The Diagnostic Features and Treatment of Leprosy

By Dr. Prince A. Morrow. The author summarizes his conclusions as follows:

1. From the standpoint of scientific therapusis, a clear conception of the pathogenesis and pathological anatomy of leprosy is an essential condition in formulating the principals of rational treatment.

2. It is now generally conceded that Hansen's bacillus is the active, efficient cause of leprosy, and that the presence of the bacilli in the tissues sets up either directly, or indirectly through their toxines, the vast array of organic changes and functional disorders peculiar to the disease.

3. There is no substance known to science which, introduced into the body, is capable of destroying the bacilli without destroying the living cells which contain them.

4. Furthermore, from the nature of the pathological changes and the position of the bacilli in the deeper tissues, it is evident that no germicidal agent can be brought into direct contact with the pathogenetic organisms, and hence all treatment which has for its object the destruction of the bacilli is impossible of application.

5. The treatment of leprosy by injections of tuberculin has been disappointing in its results. Experiment has shown that the action of tuberculin is positively pernicious in setting free the bacilli in the tissues and determining the development of new foci of the disease.

6. The treatment of leprosy is essentially empyrical; whether, as has been claimed, certain remedies act by virtue of sterilizing properties upon the living tissues, rendering them unsuitable to the growth and multiplication of the bacilli, cannot be determined.

7. The more or less rapid development of leprosy depends upon the resistance of the tissues to the inroads of the bacilli. In exceptional but well authenticated cases, this capacity of resistance is sufficient to dominate and destroy the pathogenetic microbes, as shown by the observation of abortive cases in which indubitable signs of the disease definitely disappear and never recur.

8. This capacity of resistance may be strengthened by change of climate, improved habits of living, and measures calculated to build up and maintain the general health at the highest standard.

9. Observation shows that the removal of a leper from an infected district to a more favored climate exerts a marked modification on the course of the disease; there is, for a time, at least, an arrest or retrogression of the symptoms. This lull in the manifestations is, as a rule, disappointing in its duration. Of the one hundred and sixty Norwegian lepers who have emigrated to this country, there is no record of a single definite cure.

10. A dry, moderately cool, mountain atmosphere is most favorable in its influence upon the disease. A hot moist climate, or a damp cold climate are both unfavorable.

11. A nutritious diet of fresh meat and vegetables, warm clothing, exercise in the open air, freedom from exposure to damp and cold, are important elements in the hygienic course of treatment.

12. The care of the skin by frequent hot baths, massage, with inunctions of oils, etc, should receive as much attention as the constitutional treatment.

13. The special remedies which clinical experience would indicate to be of the most value, are chaulmoogra oil, gurjun oil, arsenic, and certain agents of the strychnos family; all are, however, more or less disappointing in their results.

14. All observers agree that in advanced cases, where general dissemination of the bacilli has taken place, curative treatment is absolutely futile. The most favorable conditions are that treatment be instituted early, and that it be prosecuted actively and energetically during a prolonged period.

15. The surgical treatment of leprous sores, necrosed bones, perforating ulcers, the excision of tuberoles, amputation of the members, tracheotomy, various delicate operations about the eyes, nerve-stretching for the relief of pain, the removal of threatening complications, are of the most signal benefit.

16. Finally, we may conclude that while medical science holds out no definite promise of cure to the leper, its resources are sufficient to arrest or retard the progress of his disease, to promote his comfort, and to prolong his life.

The paper by Drs. William E. Hughes and William S. Carter entitled

A Clinical and Experimental Study of Uraemia

Is concluded in this issue. As the result of the numerous experiments the authors have come to the following conclusions:

1. Uræmia is an intoxication by a poison circulating in the blood.

2. This poison is present in serous effusions as well as in the blood.

3. It is probable that in addition to the dathogenic poison of uræmia there are, under certain conditions, other secondary ones active in its production.

4. The poison producing uræmia will also produce nephritis and a fatty degeneration of the retina, and cause of the eye symptoms in Bright's disease.

5. This poison is probably some albuminous substance. It is effected by heat and is only with difficulty dialyzable.

6. In is probable, but not certain, that this poison is not constantly circulating in the blood, but that under exceptional conditions it becomes developed.

7. It is possible to have uræmia without any previously existing lesion in the kidneys.

As to the treatment of the convulsions, the authors advise the use of chloroform, ether or nitrite of amyl by inhalation. Morphine in full doses may be used with advantage. The authors state that the use of morphia is attensed with very little risk, but its effect must, however, be carefully watched. Especially where uræmia complicates fevers must the greatest care be used, for these are the cases in which it is most likely to do harm. The bowels should be kept free, preferably with the vegetable purgatives. If calomel be used, It must be remembered that mercurial salivation is sometimes easily produced in Bright's disease. The skin should be kept active, preferably by the use of the hot pack or the hot air bath. If there is pyrexia, heat should be carefully applied and the temperature constantly watched. If there is any rise such an attempt to produce perspiration must be abandoned. Pilocarpin must be used with care for its use is not unattended with danger.

As the poison is contained in serous effusions as well as in the blood, and as resorption of these effusions may throw enough of the poison into the blood to cause uræmia, it is necessarv to withdraw effusions whenever met with, as early as possible. No condition of the patient will contraindicate tapping.

The authors also urge free venesection. They are of the opinion that it may abort an attack of uræmia. A pronouncedly weak pulse will in no wise forbid its employment, for they state that they have repeatedly seen the pulse strengthen while blood was flowing. The quantity to be drawn will depend upon the exigencies of the case and the effect produced, being, as a rule, not less than a pint, or even a quart or more. Bloodletting may be beneficially supplemented by transfusion of a normal saline solution Especially is this valuable where the loss of blood threatens to weaken the heart too much. The saline solution is also diuretic, and may possibly be a direct antidote to the poison. The transfusion may be done intra-venously in exceptional cases when time is of importance; but this may entail some danger unless most carefully performed. Practiced subcutaneously, it will be found that absorption is marvelously rapid. In a case of pulmonary œdema, where its use would be theoretically contraindicated, it was followed by a most prompt relief of the symptoms, which bloodletting alone failed to abate. Diuretics are practically of no value. The authors suggest that the origin of the poison may probably be found in the food and is produced somewhere in the digestive system. The paper is profusly illustrated.

F. Parkes Weber, M. A., M. D., M. R. C. P. (Lond.) contributes an article on "The Pathology of Arterio-sclerosis", in which, after considering various hypotheses, he confesses that the etiology ot arterio-sclerosis remains as yet uncertain. The condition must still be regarded as a primary one in pathology, though in some way allied to some of its alleged causes.

The remaining papers in this issue are: "The Therapeutics of Infectious Processes in the Nervous System," by F. X, Dercum, M. D.; "Foot-ball and the Physique of its Devotees, from the Point of View of Physical Training," by Henry G. Beyer, M. D., Ph. D., Surgeon U. S. Army.

Nævi and Maternal Impressions.

Since the days when a certain historic progenitor made large capital out of peeled saplings and probably from an even remoter age than his, there has existed, says the *London Lancet*, among mankind a belief in the causation of birth-marks by previous maternal impression. A singular illustration of this fact is to be found in a case lately recorded by one of the American papers. The mother, an Italian, while pregnant, was frightened by seeing a snake among some fruit she was handling. In due time her child was born, and from birth displayed a peculiar mark upon the neck. This gradually assumed the form and appearance of a serpent, was deeply pigmented, and somewhat scaly. The tale is, indeed, a strange one. Had it come through any less reliable channel than a publication of the Transatlantic press we should probably have dismissed without question its pretensions to veracity. As it is we cannot resist the impression that facts and appearances must have been much exaggerated and altered since the original facts of evidence went on the ever widening circuit of rumor. Nævi, it is well known, may occupy any part of the surface of the body, may vary indefinitely in shape, are usually pigmented, and frequently possess a thickened and rough integument. In view of these facts it is difficult, even with the aid of a description almost circumstantial enough to find the mimic snake its place among the Reptilia, to resist a conviction that imagination has done much in this history to give color and shape to a clinical curiosity. The whole theory of maternal impression, however appropriate, beautiful, or strange, partakes of a character too nearly related to allegory to secure for its revelations a place among the accredited discoveries of science.—*Maryland Medical Journal.*

MEDICINE

Snuff-Tobacco as a Remedy Against Hiccough.

In the *Vratch*, No. 14, 1894, p. 423, Dr. G. Tatevosoff, of Vozdvijenskaia Slobada, Caucasian Russia, draws attention to the excellent services which may be obtained from the ordinary snuff-tobacco as a means for cutting short hiccough. He relates an instructive case of a patient with some chronic chest disease, accompanied by violent cough attacks in whom the latter used to be followed by extremely obstinate hiccough. The common remedies (including cocaine) failing to exercise any controlling influence on this most distressing symptom, Dr. Tatevosoff at last decided to give a trial to the said old-fashioned popular means, making the patient on each occasion thoroughly snuff into his nose a pinchful of the powder until the appearance of a lively sneezing. From the first *seance* "the effect was truly brilliant, the hiccough subsiding as if by magic." Under the influence of the simple remedy the attacks steadily became milder, and ultimately vanished, though the patient's cough remained as intractable as ever.—*St. Louis Med. and Surg. Journal.*

The Effect of Ether and Chloroform on the Kidneys.

Wunderlich (*Annals of Surgery*,) after the examination of the urine in 125 cases, before and after anæsthesia, draws the following conclusions as to the effect of ether and chloroform narcosis on the kidneys:

1. An already existing albuminuria is often increased by etherization. No such case in which chloroform was given was observed.
2. Albuminuria can be caused by narcotization with chloroform and ether, more often with chloroform, the relative frequency with which it occurs after the use of chloroform and ether being 11.5 to 6.9.
3. As a result of the use of chloroform, casts may appear in the urine. This is less frequent after the use of ether. The relative of frequency is 34.8 to 24.6.
4. When casts are already present, both anæsthetics have the effect of of increasing the number.—*Boston Med. and Surg. Jour.*

SURGERY.

The Dangers of the Long Rectal Tube.

The use of the long rectal tube in cases of obstruction, or supposed obstruction of the bowel, has never been looked upon with favor by good anatomists. The finding of the traditional needle in the haystack is but little more difficult than the successful maneuvering of the rectal tube through the twists and turns of the sigmoid flexure. The question of the value and safety of this tube having been asked of the *British Medical Journal*, the matter was referred to Mr. Harrison Cripps who replied as follows to that journal:

Traditions die hard, and notwithstanding the condemnation of the long rectal tube by Brodie, Treves and many other eminent authorities, I still find that in most cases of obstruction or supposed obstruction the tube has been introduced. Fortunately, these tubes are fairly soft, so that in a capacious rectum, when they impinge and are arrested about opposite the promotory of the sacrum, they simply coil up and do no harm. If stiffer ones are used, the patient's life is placed in imminent risk. A patient at St. Bartholomew's Hospital was to be operated on for ruptured perineum. In order to increase the supposed efficacy of the injection, a quart of soap and water, with some ounces of oil, were injected by means of a long tube. The injection never returned. A few hours afterwards, owing to the acute symptoms of the patient, I assisted one of my colleagues in opening the abdomen. The soap and water and oil we found in the abdominal cavity, and a hole below a reduplicated fold in the upper part of the rectum. The patient died. The idea that these tubes can be generally passed into and beyond the sigmoid flexure is a pure delusion, save in the rarest circumstances. As a means of diagnosis, or of treating stricture beyond the reach of the finger, tubes of any kind are absolutely useless. If a stricture is actually present, it would be 100 to 1 against the long tube or bougie entering it, for it would almost certainly catch in the cul-de-sac, generally caused by the invagination of the stricture. If a stricture be not present, the arrest of the bougie by the sacral promontory leads to delusive diagnosis. Brodie, in his lectures, alludes to a case in which a worthy practitioner had spent 150 hours in dilating a supposed stricture situated high up. The treatment had extended over a period of a year. Brodie, who was present at the post mortem examination, found there was no sign of a stricture, the bougie becoming arrested by a curve of the sacrum.—*Columbus Medical Journal.*

The Treatment of Fracture by Massage.

Sevenin, of Moscow, reports 24 cases of fractures treated by massage, and claims a great future for this treatment. To hasten union he gives three times daily a powder consisting of two grains of phosphate of iron and five grains of phosphate of lime. He demonstrates the beneficial action of this powder in relating his last four cases which took an unusual short time in healing. One of these cases, a fracture of the surgical neck of the humerus in a washerwoman of fifty-two years of age, showed no more crepitation on the eighth day, the abnormal mobility had ceased, and on the sixteenth day the patient could raise her arm in a horizontal position.—*Pacific Med. Journ.*

OBSTETRICS.

Diagnosis of Early Pregnancy.

Dr. R. L. Dickinson makes an interesting report of original investigations made by him to discover how early pregnancy may be diagnosed. He relies entirely upon the bimanual method of examination. It is easy to see that an expert in this method of examination, and one who has plenty of material, could certainly make a diagnosis at an earlier period than is usually the custom with practitioners. Dr. Dickinson concludes his article as follows: We offer then tentatively six bimanual signs of early pregnancy, stated in the order of their appearance and importance, and in the order of the frequency with which they are found, they run as follows (except that compressibility of the isthmus and the change of the consistency of the body possibly outrank the rest):

1. Bellying or bulging of the body of the uterus.
2. Elasticity or boggyness of the body of the uterus.
3. Compressibility of the lower uterine segment.
4. Transverse fold (about four to six weeks).
5. The longitudinal fold or furrow.
6. The decidual spot (about six to eight weeks).—*Atlanta Med. and Surg. Journ.*

Glycerine Injections as an Oxytocic.

Pelzer (*British Medical Journal*) read a communication on this subject at a recent meeting of the Cologne Obstetric Society. He had collected 28 cases, including 19 in his own experience. Glycerine was used 18 times for induction of premature labor; in 15 of these cases the pelvis was narrowed, in 2 there was Bright's disease, and in 1 placenta previa. To stimulate uterine action at term glycerine was injected in 7 cases of simple atony, in 2 of placenta previa, and in 1 for some other complication. The pains came on after an average interval of two hours following the injection. Eight to ten hours elapsed before complete dilatation of the os, or a longer space of time in cases of contracted pelvis. Two of the mothers died, both from severe eclampsia; the fetus was putrid in both cases. One child required craniotomy on account of its great size. Three children died from placenta previa and strangulation by the funis. One, hardly 32 weeks old, died a quarter of an hour after birth. Only in one case could the violence of the pains be a possible cause of the death of the child. The glycerine had done its duty. Pelzer, however, deprecates injudicious zeal about this method; 30 to 50 cubic centimetres, not 100 cubic centimetres, are sufficient for injection. The method is not suitable for cases of eclampsia and placenta previa, except the lateral variety, where the placenta can be avoided. —Geuer (*ibid*) read notes of three cases of induction of premature labor by injection of glycerine, in all of which both mother and child were saved. The first two mothers were over 32, with contracted pelvis; craniotomy had been performed in previous labors. The third case was an instance of bad eclampsia; 40 grammes of glycerine were injected, the os being at the time uncontracted; there was edema, with much albuminuria. Forty hours later a healthy living child was born.

ARMY AND NAVY.

CHANGES IN THE U. S. ARMY FROM SEPTEMBER 2, 1894, to SEPTEMBER 8, 1894.

Leave of absence for twenty days to take effect October 10, 1894, is hereby granted Captain Jefferson R. Kean, Assistant Surgeon.

Leave of absence for one month, to take effect on being relieved from duty at Washington Barracks, D. C., with permission to apply for an extension of fifteen days, is granted Major Joseph K. Corson, Surgeon.

Leave of absence for four months on Surgeon's certificate of disability, is granted Major Washington Matthews, Surgeon.

Leave of absence for one month and fifteen days to take effect on or about September 10, 1894, is granted Captain Charles B. Ewing, Assistant Surgeon.

First Lieutenant James M. Kennedy, Assistant Surgeon, will be relieved from duty at Fort Custer, Montana, and will report in person for duty at Camp Merritt, Montana.

ORIGINAL ARTICLES.

FOREIGN-BODIES IN THE EAR: A WARNING.

ROBERT BARCLAY, A. M., M. D.,* St. Louis, Mo.

A patient, his relatives or friends, may often declare sincerely, under a positive conviction of its truth, that there is a foreign-body in the ear, and may importune—Nay! even demand its immediate dislodgement by interference at the hands of the medical practitioner. This is one of those crises where the physician must not lose his self-command; must be deliberate; must stand firmly on the rock of our calling, "*Be sure you're right; then go ahead!*"

Except when there is adequate reason for presuming that there is a live insect, or a corrosive chemical, within the ear, producing intolerable pain—where avoidable delay would be unnecessarily cruel, since an immediate instillation of or gentle syringing with warm water may give instantly temporary relief, with the least possibility of an injury to uninvolved parts,—with that exception: No matter how positive a patient, his relatives or friends, may be, that there is a foreign-body in his ear, never attempt the removal of such until you have first provided yourself with satisfactory illumination of the canal, examined the ear thoroughly by ocular inspection, and convinced yourself of the presence of a foreign-body.

To apply this rule invariably, with but the single exception above noted, is to protect the best interests of your patient and yourself; to disregard it, is to court disaster, as experience demonstrates not infrequently.

"How *not* to do it," and its consequences, are well illustrated by the following, from the writer's aural records:

Suspected Bug in the Ear; Drumhead Injured by Mal-treatment.—This gentleman (404102) on experiencing some unusual fluttering sensation in his right ear, thought that a bug had flown into it, and forthwith "poked at it with a pin," hoping to dislodge the suspected intruder. Failing in this, he sought the assistance of his office-boy, who also, employing similar measures, failed. Immediately thereafter, our patient consulted a reputable physician, who "worked at it in vain for an hour; poked it, and syringed it repeatedly," until discouraged; and "put no cotton into the ear after syringing."

The "movement of the bug" (?) persisting, and the ear having begun to ache, the patient was referred to the writer for further advice and assistance.

The above is substantially the statement made by the patient at our consultation, the following morning.

On careful examination at that time,

* Member of the American Otological Society; formerly Assistant Aural Surgeon, New York Eye and Ear Infirmary, New York; Aural Surgeon, St. Louis City Hospital, Missouri Pacific Railway Hospital, St. Louis Baptist Hospital, St. Mary's Infirmary, South Side Dispensary, Mariæ Consilia Deaf and Dumb Institute, House of the Good Shepherd, Etc.

the parts were found (Fig. 1) congested; particularly so, the manubrial plexus of blood-vessels. There was an abrasion of the postero-superior canal-wall, near the drum-head. A spot, resembling a traumatic perforation of the drum-head, just healing, was found just behind and on a level with the middle of the handle of the malleus. Whether this was really a perforation, or merely an abrasion of the drum-head, might readily have been determined; but would have necessitated, therefor, a displacement of the parts. And, inasmuch, as these seemed already disposed as favorably as possible for repair with least resultant deformity, it was deemed inadvisable to disturb them merely for the purpose of determining that question.

There was *no foreign-body* in the auditory canal!

Except for a gentle application of Succus calendulæ to the wounds, the ear was not disturbed; and complete recovery ensued within a few days.

FIG. 1.

Suspected Pebble in the Ear; Drum-head and Canal-wall Injured by Mal-treatment.—The mother of this three-year-old boy (104 275) took him to a physician, stating that he had "got a pebble into his right ear;" that his sister, five-and-one-half-years-old, had "put the pebble into his right ear at least they said she had;" that on examining the ear herself, and seeing what she believed to be the pebble, she had "tried" in vain "to get it out with a hairpin," until warned to desist by the child's complaints of "its hurting him." The pebble, she said, was by that time beyond sight. The little fellow experienced no special discomfort until his visit to the physician, who, presuming upon the mother's statement (substantially repeated above) and without making ocular inspection, attempted to dislodge the pebble by probing or raking the depth of the auditory canal with a steel-scoop or ear-spoon. He failed; but persisted in the attempt until impelled to desist by the screams and struggles of the child.

On the following morning this procedure was repeated, but more vigorously, by this physician; an efficient corps of "assistants" being employed to "hold" the little victim. Notwithstanding, the foreign body was not dislodged; but a "scraping sound" and a profuse hemorrhage rewarded the efforts at extraction.

The patient was taken by his mother, late on the same day, to another physician, who finding the ear badly injured, the condition of the parts unfamiliar, and the patient unmanageable, referred the case to the writer.

The terror of the child at our first consultation was pitiable, and was not surprising when the mother had stated, besides the above, that "she knew there was a pebble in his ear, for she had heard the instrument of the [first] doctor scrape against it while poking his ear." The sero-sanguinolent discharge from the meatus, of course aroused the writer's suspicion that the "scraping sound" had probably been that produced by the rasping of instruments upon forcibly-denuded bone,—doubtless upon the osseous auditory canal.

Informing the mother that if a foreign-body were present within the ear, and if the patient should, under my treatment, remain so restless and unmanageable, removal would have to be attempted under general anæsthesia; the writer advised a policy of gentle conciliation and mild treatment for a little. At the consultation, therefore, although the ear was discharging sero-sanguinolent fluid, nothing further was attempted than to gain the good-will and confidence of the little patient. This attempt was so far successful that at the next visit, upon the following morning, he allowed a gentle aural insufflation of powdered Boracic acid, and the placing of a wad of absorbent cotton in the concha of the injured ear. At the next, an afternoon visit, he allowed the introduction of a speculum, and a partial removal of the discharge with the cotton dossil. Thus, gradually, his confidence was gained, and at a thorough examination which he submitted to, a little later, it was discovered that the soft parts of the postero-superior canal-wall near the drum-head, together with the neighboring por-

tion of the membrana flaccida and vibrating drum-head, had been torn away from their bony attachment, and were flapping loosely in the discharges that filled the lumen of the auditory canal. The postero-superior osseous canal-wall was found partially denuded; and it was doubtless here that the impact of instruments had made the "scraping-sound." *No foreign-body* was found within the ear. After dressing the parts for a day or two with powdered Boracic acid until this last fact was demonstrated to his satisfaction, the writer explained the aural condition to the mother, informing her that he could find no foreign-body within the ear, and expressed the opinion that it was probable that she had been mistaken as to there having been one there. Her spirited denunciation of his ignorance and clumsiness in failing to discover the condition of which she had become so firmly convinced, and her rash threat of "getting *some* one to get the pebble out!" elicited from him a serious warning to the effect that "if she had been as positive and as importunate with the other Doctors as she had been with him, they were the more excusable for having done what he confidently could and would positively refuse to do;" and that "if she should obstinately persist in having the little boy's ear scraped for the removal of a foreign-body—which was not there—the suffering, and the deafness, and perhaps even the death of her child would be upon her own head, and due solely to her own obstinate and unreasonable prejudice respecting this matter of fact of which she had conclusively proven herself—as she naturally should be — incompetent to judge."

She did not return until weeks afterward, when she informed the writer that she had discontinued medical treatment with her preceding visit to him; that, "except for his otorrhea, the boy had sufferred no further discomfort from the presence of the pebble within the ear, which had not yet been removed," (?) but that "maybe the writer was mistaken about it, for she felt confident that it was still there." (?) Whereupon, with a few remarks as to the prognosis in tympanic abscess, the foregoing warning was repeated—and the case drifted into more obsequious, doubtless more skillful hands!

Instructive cases these! whose lesson, from a practical standpoint, is obviously that implied in the proverbial: "How to cook a *hare*. First—*Catch* your hare!" liberally translated for our purpose: To *remove* a *foreign-body* from the ear. First—The *foreign-body actually within* the ear. To sum up: As with every other abnormal or morbid condition, whatsoever and wheresoever, *so with foreign-bodies in the ear*: Diagnosis, *first*; TREATMENT, LAST!

THE ANTISEPTIC DRESSING OF THE UMBILICAL STUMP.

HIRAM CORSON, M. D., PLYMOUTH MEETING, PA.

In the editorial pages of the *Journal of the American Medical Association* (April, page 634) reference is made to an earnest plea, made by Dr. Joseph Allen (*American Journal of Obstetrics*) for more care of the cord in new-born children, and the article commended. And what does Dr. Allen recommend?

"The cord is ligated temporarily or clamped till after the nurse has washed the child. The accoucheur, having previously washed his hands and the child's abdomen and cord in an antiseptic solution, releases the ligature, strips the cord, pressing out as much of the contained gelatinous material as possible, and religates it with a silk ligature that has been rendered thoroughly antiseptic by being boiled in a strong solution of corrosive sublimate and afterward kept in a solution of iodoform in ether. The cord is then dressed with a piece of sterilized gauze, covered again with a pad of gauze soaked in chemically pure glycerin, and the whole retained by a sterilized flannel bandage. Each day the pad is removed and a fresh one, soaked also in glycerin, applied; as often as the retaining band becomes soiled it is changed."

Some months since an obstetrician and writer of much merit, published a paper, in which not an earnest plea, but pointed or-

ders were given to every physician who expects to be called to a case of labor, "to visit the patient at least three months before the expected time and make a careful *per vaginem* examination and an external abdominal one, to see if there are defects in the genital organs, or wrong position of the child to be corrected; and that these visits and examinations should be repeated at short intervals until the labor is near at hand." I have neglected to mention an inquiry and examination to which he referred; namely, "to ascertain the condition of the kidneys; whether or not there are threatenings of Brights Disease." All these visits and examinations are to be made by a doctor rendered thoroughly antiseptic from head to toe.

Now, while I consider this unasked—for interference, this securing a patient and loading her with a heavy medical bill, wholly unjustifiable, there is even a weightier objection to it. It frightens the patient. So earnest is the doctor, so positive are his objections, so frequent his visits, so alarming the fact that the urine must be so often examined, that the poor woman's fears are excited to a degree that makes her nervous and unhappy, when she otherwise would have gone on from day to day hopeful and joyous.

But you ask, "Why drag this subject into a review or criticism of the paper of Dr. Allen?" Simply because we are throwing around the natural and successful process of labor, requirements not needed in more than one case in fifty—if, indeed, so many as one—and because in cities—medical centres—women are made unhappy by such interference, such prognostics of danger if they do not strictly observe all the physician's details.

Now, about the care of the cord. This is a proper subject to think about. Dr. Allen has, yet, something to learn. I infer that he ties the cord directly after the child is born, cuts the cord and then hands the child to the nurse. Years ago, between 1860 and 1870, some of the members of our County Society, instead of tying the cord, cut it at once and let the blood fly—as it sometimes did to a distance of several feet. When it ceased to bleed, some left it without tying, while others, fearful that it might possibly bleed, secured it by a common thread ligature. My mind being thus called to the subject, I felt that it was wrong to spill so much of the blood that belonged to the child, and I resolved to see how much would be lost by cutting, or, which produced the same result, tying it soon after its birth, as seems to have been the habit of Dr. Allen. To ascertain how much blood is lost to the child by cutting the cord soon after the child is born, I (Case 1.) cut the cord of a healthy male child three inches from the navel, in two minutes after it was born I caught two ounces of blood from the cut end of the cord.

Case 2.—Female; caught two ounces in three minutes.

Case 3.—Male; caught two and a half ounces.

Case 4.—Male; caught slightly more than two ounces.

In every case there were more than two ounces, for I first caught it in a bowl and then poured it into a graduated glass. In doing this, some adhered to the bowl and some was lost.

Is it a matter of indifference whether the child is robbed of this blood or not? How is it disposed of in a natural case when the doctor is not present? It flows from the umbilical vein without hindrance into the body of the child; the cord collapses by a natural contraction; generally within a half an hour the pulsation of the umbilical arteries cannot be felt in the umbilicus of the child, and the cord, white, flaccid, shrivelled and without a drop of blood in it, lies before the observer. Here is where Dr. Allen, by tying the cord, is doing wrong. Had he let the cord alone until the pulsations had ceased, he need not have squeezed out any gelatinous matter. A child thus treated is in no danger from hemorrhage. The small, flaccid, bloodless cord dries and falls off in a few days, without a drop of pus being formed, without need of aristol or gauze pad—much to the disgust of the microbe—and without the officiousness of the obstetrician.

In the transactions of the Pennsylvania State Medical Society for 1872, I have reported thirty-four cases in which I observed the time during which the pulsations of the umbilical cord could be felt in the vagina before the placenta was expelled, and for how long a time they could be felt at the navel of the child. The circulation of the blood continues in the placenta until it is separated from the side of the womb, and even in cases where the

placenta quickly follows the child, the circulation may go on for many minutes. After a short time the arteries of the cord fail to force the blood to the placenta, and gradually the blood recedes until the pulsations cannot be felt in the stump—the projecting umbilicus. For many years, in view of these facts, I have waited before tying the cord until the blood in the vein had all passed into the child and the contraction of the arteries, beginning at the placenta, had gradually prevented the blood from the child's heart being forced into the arteries of the cord. I have, therefore, needed no antiseptics, and the fiendish microbe was not to be seen in that region.

I know by actual experience from repeated trials that, if the cord be not tied until after the blood has passed from the umbilical vein into the body of the child, not a drop of blood will escape from it if, afterward, it be not tied.

In view of these facts physicians should have patience; should allow a few moments to pass before tying the cord. Then they would see the cord which was turgid with the fullness of blood, lying empty; a white, flaccid, shrunken thing, which may be cut without fear of a single drop of blood coming from it. If when you take hold of the stump, as I call the then fleshy projection, the pulsations of the arteries can be felt between the thumb and finger, one must wait a little longer—and when this cannot be felt, one will then know that there is no danger of bleeding from the cord.

If it be important in this attention to the woman to insure her safety according to Dr. Allen, and so important in the opinion of the other writer that such elaborate measures as washing the child's belly with corrosive sublimate solution and using gauze pads, etc., be needed to avoid ulceration of the navel of the new-born child, why shall not the accoucheur give a few minutes of time to waiting for the blood to get into the child's body, when it will be secure from hemorrhage or having a sore navel.

It is painful to me to see enlightened physicians, even teachers of obstetrics, carrying on the old plan of tying the cord instantly after the birth of the child, when waiting for a short time would obviate the need to tie it at all.

I need not comment on the wrongfulness of these numerous measures and the danger of these washings with the poisonous corrosive sublimate solutions. The fact that millions of children born in our country every year do well without such measures must prove the impropriety, needlessness and danger of them.

CHRISTIAN SCIENCE AND MEDICINE.*

J. N. HUNSBERGER, M. D., SKIPPACK, PA.

It is a well-known fact that primitive man from time immemorial has allowed his thoughts and actions to be governed by the supernatural. The changes from day into night, the different phases of the moon, eclipses, storms, droughts, floods, in fact all changes that followed nature's laws were to him the display of the love or anger of whatever supernatural being he chanced to worship. And the cannibal, who today prostrates himself before his pile of stones, worships his god no less intensely or devoutly than does civilized man under the highest enlightened conditions of society. The difference is in environments, not in degree. The savage is satisfied with what seems an answer to his petitions, in the gratifications of his few wants. Civilized man is usually dissatisfied because all his petitions are not answered.

Huxley tells us, "suffering came into the world, not in consequence of a *fall*, but of a *rise* in the scale of being; so every further rise has brought more suffering. The amount and severity of the pain, no less than the variety and acuteness of the pleasures, have increased with every advance in the scale of evolution." Just as the highly sensitized plate of the camera reproduces quickly and accurately any impression made on its surface, so does

*Read before the Montgomery County Medical Society, May 9, 1894.

the exquisitely sensitive nervous gray matter of the highest grade of enlightenment reflect impressions, quickly and acutely, that cause pain or pleasure as the case may be. That we are steadily rising, steadily evoluting, no one can successfully dispute.

Let us quote again from Huxely: "The doctrine of evolution implies indeed a former state of innocence of mankind, but it is the innocence of the ape and of the tiger, whose acts, however they may run counter to the principles of morality, it would be absurd to blame. It is a reasonable supposition that in the earliest human organisms an improved brain, a voice more capable of modulation and articulation, limbs which bent themselves better to gesture, a more perfect hand, capable among other things of imitating form in plaster or other material, were combined with the curiosity, the mimetic tendency, the strong family affection of the next lower group."

But in spite of this mental and physical evolution we are, so far as our emotions and beliefs are concerned, not so distantly removed from the lower strata of mankind. We still believe Friday to be an unlucky day. We have not forgotten the superstition of the first glance at the new moon. We still pay our good dollars to be cured by quacks. We still believe the testimonials of wonderful cures effected by taking one bottle of somebody's patent medicine. We still go to Paris to be hypnotized or to be inoculated for hydrophobia. We still believe, as they did in the time of the Pharoahs, that charms, incantations and amulets will drive away all aches and pains, if only these charms, incantations and amulets can be called "by any other name."

> "But faith, fanatic faith, once wedded fast
> To some dear falsehood, hugs it to the last."

There is something so pathetic, because so intensely human, in the blind belief that draws thousands and tens of thousands of suffering humanity to pay homage to the Grotto of Lourdes and bathe in its holy waters. That thousands are temporarily relieved or permanently cured, the numerous crutches that decorate the walls of the grotto testify. When even royalty tramp about in the morning dew with naked feet, guided by an ignorant monk, we can to a certain extent sympathize with some of the superstitions of the less educated classes. Or, when such men as Brown-Sequard, with his expressed juice of the testicle, attempts to inject new life into the wreck of a man, we are forcible reminded of "when all others fail consult Dr. Snobb." Or, when Hammond, with his compressed extracts of brain, liver, lungs, ovaries, etc., attempts a cure by giving some of the hair of the dog that did the biting. Or, possibly, when Pasteur and Koch, with their lymph and hyperdic syringe—but why give you post-mortems. And yet these men represent the best in medicine, stand at the very top of the profession. "They do bestride the narrow world like a Colossus, and we petty men walk under their huge legs, and peep about to find ourselves dishonorable graves." They have thrown out a tempting bait; they have been rewarded with a nice string of suckers—more than a nibble.

It is the insane desire for something new, some royal road to success, that leads so many investigators to make misleading statements, arrive at false conclusions. The people demand something new in all the arts and sciences, and usually get it—such as it is. The press caters to this unnatural appetite; all sorts and conditions of men furnish the food, and there you are. Take your choice—hypnotism, hoodooism, faith cure, christian science. They are all practically the same; they have one common end in view. And so long as "faith is a higher faculty than reason," just so long will they create new diseases and invent new cures. "Even the earnest Charcot was accused of manufacturing new types of invalidism by his scientific performances at the hospitals, while some common doctor will rescue case after case by using methods which are not medical, but pedagogic and moral."

There is nothing new about christian science except its name and a few little details that are made to stand out so prominently as to conceal the identity of the old-fashioned faith cure. Christian science claims that the body should be at all times subservient to the mind; that if the mind wills it strong enough, the whole army of micro-organisms which are claimed to be the cause of infectious diseases, will be unable to gain entrance to the body. In fact it makes the human organisms a more impossible culture medium than a saturated solution of bi-chloride of mercury. As a lecturer

on christian science answered, in reply to the question, "What would be the effect on a person of a highly poisonous dose of strychnine?" "If the individual who took the dose had enough faith, the poison would be harmless." But, the lecturer added, it would require years of training in the art of christian science before the person would have faith enough to stand such a test.

This is simply absurd, and yet it is not any more absurd than some medical fads that have had a following in their day. The trouble is the pendulum has swung too far. Just at present, the awful danger of contracting phthisis has become the fad, and precautions, as ridiculous as they are unnecessary and annoying, are heaped on the stricken ones.

That christian science has a following of some of the most intellectual people, is uncontrovertable. It is a truth, that as we advance in the scale of enlightenment we still cling to the supernatural, but we demand that our ghosts come to us dressed and in their right minds. As Thomas Carlyle, in Sartor Resartus, so aptly puts it, "Witchcraft and all manner of spectre-work and demonology, we have now named madness and diseases of the nerves, seldom reflecting that still the new question comes upon us: What is madness; what are nerves? Was Luther's picture of the devil less a reality, whether it was formed within the bodily eye or without it? In even the wisest soul lies a whole world of internal madness, an authentic demon empire, out of which, indeed, his world of wisdom has been creatively built together, and now rests there; as on its dark foundations does a habitable flowery Earth-rind."

Every thinking medical man must realize that we are tending slowly but, nevertheless, surely, to therapeutic measures that have as their basis of treatment the patient's mind itself. I refer principally to morbid nervous troubles, of which we know but little. Just what these therapeutic measures should be is as yet undiscovered, but that potion and pill will enter into their makeup, I do not believe. They will have a great deal of opposition. "We are, as was Ephraim of old, wedded to our idols; we want to be let alone." We prefer to see our fellow beings suffer than to see them cured in an irregular way. We can't understand how an ignorant quack can cure (?) hydrophobia, while the scientific Pasteur loses 25 per cent. of his cases.

I believe that in the near future there will be a chair of psychology in every medical school in the world, where the best methods of securing control of the patient's mind will be taught. It will open a field hitherto undreamed of in the science of medicine. For if ignorant, uncultured charlatans can effect such wonderful cures, what may not be accomplished with the best minds of the medical profession directed to the subject. And what a training will be necessary for the scientific faith cure; what a study of mankind; what an opportunity for the development of individuality, and what a pleasure to know that your patient's mind is to you an open book, on whose pages you may inscribe the way to health.

Antiseptic Ointment.

After delivery in placenta prævia Dr. Q. C. Smith is in the habit of applying to the external genitalia:

℞

Olei pini pumilionis	
Olei sassafras	
Olei Camphor	ää ʒij
Olei cinnamon	ʒj
Sacchar. alb. in very fine powder	ʒiv
Lanolin	ʒviij

Mix well and make ointment.
Sig.: Apply as directed.

—*Virginia Medical Monthly.*

For Chronic Catarrhal Diarrhœa.

℞

Extract of rhatany	1 drm
Syrup of morphine	
Syrup of quince, each	12 drms
Lime-water	q. s. to 5 ounces

℞

Liq. perchlor. of iron	8-15 grains
Sydenham's laudanum	20-30 drops
Mucilage of gum arabic	
Simple Syrup, of each	1 ounce
Cinnamon distilled water	q. s. to 5 ounces

Sig.: Dessertspoonful every two hours of either of the last two mixtures.

—*Ther. Gazette.*

Diarrhœa.

Sapelier presents the following formulæ:

℞

Lactic acid	5 drachms
Simple syrup	6 ounces
Boiled water	1 quart

℞

Subnitrate of bismuth	8 ounces
Carbonate of calcium	
Phosphate of calcium	
Powder of rhatany, of each	2 ounces
Powder of crude opium	45 grains

M. Sig.: Two or three dessertspoonfuls a day, given in the lactic-acid solution.

COMMUNICATIONS.

LAPAROTOMY FOR RELIEF OF INTUSSUSCEPTION; WITH REPORT OF A CASE OCCURRING IN A CHILD ÆT. NINE MONTHS.

W. O. ROBERTS, M. D., Louisville, Ky.

On Tuesday, April 26th, at 12.30 p. m. I was called by Dr. Turner Anderson to do a laparotomy for intussusception. Dr. Henry Heuser, who happened in my office as I was starting, accompanied me. On reaching the house, we learned from Dr. Anderson that he had seen the case for the first time at 11 o'clock, and after a fruitless attempt to reduce the intussusception he advised a laparotomy and telephoned for me. The child had been sick since the Friday morning preceding our visit.

The child was nine months old, a girl, had always been perfectly healthy and was well developed. The attack came on suddenly without any assignable cause. It presented the usual symptoms, viz., intense paroxysms of pain, frequent straining at stool with passage of blood and mucus, and frequent vomiting. The intussusceptum extended to the anus, and was very deeply congested. A sausage-shaped tumor could be distinctly outlined in the left side of the abdomen; the abdominal cavity was but slightly distended. The intussusceptum could be pushed up as far as the finger would reach with perfect ease. While going under cloroform the straining effort forced the intussusceptum two inches outside the anus. As before stated it was quite deeply congested, but no ulcerations or excoriations were detected.

Notwithstanding the feeble condition of the child's heart, a laparotomy was performed. The abdomen was quickly opened in the median line between the unbilicus and symphysis, and the tumor was found a little below and to the left of the umbilicus. After gentle traction assisted by Dr. Anderson pushing from below the intussusception was relieved. It proved to have started at the cæcum, which had extended clear through the colon and the rectum taking with it the ileum and its mesentery. No injury was done the gut in the operation and it seemed to be in good condition after the intussusception was relieved. The child became pulseessl during the operation and a number of hypodermatic injections of whiskey were given. It was on the table only about twenty-five minutes. After being put to bed it was given morphine and atropine hypodermatically, and for a while rallied considerably, but finally began to sink and in a few hours, like the majority of such cases, it died.

In looking over history of intussusception I find that according to Treves three-eights of all casses of intestinal obstruction are due to intussusception. Heusner puts the proportion at three-fourths. The American Text Book of Surgery says thirty per cent., excluding cases due to herniæ and malformations, and Moullin estimates it at about one-third. Fifty per cent. of the cases occur in children under the age of ten years, and twenty-five per cent. in the first twelve months of life. Eustace Smith says that obstruction is rarely due to any other cause in children. Of fifty-two cases collected by J. Lewis Smith, thirty-one occurred during the first year of life. Hare, in his late work, says it is the commonest of all causes of obstruction, and during the first year of life it is more common than all the other causes combined. After the age of five years it becomes comparatively rare until the fortieth or fiftieth year, when it again increases in frequency of occurrence. During the first year of life it is met with more frequently in boys than in girls, in the proportion of about three to one, but as the age increases the relative disproportion gradually diminishes. Under twenty months of age those that are attacked are usually sturdy and well nourished children, while in older ones it is more frequently met with in those that are run down in health from some intestinal disorder.

Rilliet attributes this comparative frequency in infants to "the looser connec-

* Read before The Louisville Medico-Chirurgical Society.

tions of the cæcum in the iliac fossa at this age, and also to the imperfect development of its muscular bands which lessens its resistance to the penetration of the small intestine into its interior." J. Lewis Smith, I think, gives about the best explanation of the comparative frequency of the disease in children. He says "it is due partly to the anatomical character of the intestines in this period of life, and partly, doubtless, to the fact that there are more frequent irregularities in the intestinal movement than in older children. In fact the walls of the intestines are thin, the mucous and muscular coats and the connective tissues being much less developed than in those that are older; the mesentery and the meso-colon have also greater depth as compared with the same in other periods of life, except the meso-colon at the points where it passes over the kidneys, in which places it is very short, or even in some cases nearly absent. Moreover the space occupied by the large intestine, in which part of the digestive tube intussusception commonly occurs, is shorter relatively to the length of the intestine than in those that are older." In about thirty measurements which he has made of the length of the large intestine and the space occupied by it, the latter was found in the average about one-third that of the former, which, of course, necessitates doubling of the intestine on itself.

The varieties as to location are ileo-caecal, where the cæcum and ileum are turned into the colon; ileo-colic, where the ileum passes through the ileo-cæcal valve and finally brings along with it the colon; the colic, in which the colon alone is involved, and the enteric, where the invagination is located entirely in the small intestines. The ileo-colic is by far the most frequent. Treves says about seventy per cent. of all cases in babies are of this variety. After invagination takes place, peristaltic movements are excited and the intussusceptum is pushed farther and farther until frequently it protrudes through the anus.

In the case reported by Harrison Cripps (*Lancet*, June 2nd, 1888), "the patient, a child seven months old, was admitted to the hospital with the bowel in a gangrenous condition, protruding from the anus. It sloughed away gradually, and at the end of a month the case was discharged cured. The child afterward died of scarlet sever, and at the autopsy the small intestine was found attached to the anus. There were no traces of the ascending, transverse or descending colon."

In about one-half of the cases the children are in perfect health and the attack come on suddenly without any assignable cause. Most authorities claim diarrhœa, colic, tenesmus from any cause as constipation, polypus, phimosis, etc., play a considerable part as etiological factors. Jacobi and others deny this. Some cases seem traceable to falls. Jacobi reports one case that was produced apparently by a child being jumped up and down in it's nurse's arms.

SYMPTOMS AND TREATMENT.

The symptoms usually come on suddenly and with great violence, especially is this the case when invagination occurs at the ileo-caecal opening. The symptoms are much less severe when invagination is located in the colon. Pain is paroxysmal in character, due to the irregular peristaltic action of the bowels, and the paroxysms steadily increase in frequency and severity. Vomiting is a prominent symptom, not so marked, however, as in strangulated hernia, in the beginning of the attack, but after a while it becomes very marked. The abdomen at first is not tender, and slight pressure seems to give comfort to the patient; after a while when inflammation occurs, of course it becomes exceedingly sensitive. It is not always distended. In the beginning of the trouble there is not complete occlusion and the consequence is that distension is not marked, but after swelling takes place the lumen of the protruded portion becomes obliterated, then distension becomes very marked. In these cases, if not relieved, inflammation occurs and in a small proportion sloughing of the intussusceptum takes place, and in cases where this does occur, about forty-one per cent. recover. Many of these, however, afterward die from perforation of the cicatrix. A tumor can be detected usually in about one-half the cases. The prognosis is very bad.

In the American Text Book of Surgery it is claimed that about eight per cent. of the cases treated medically die. Treves gives the mortality in 133 recorded cases, where radical operations were performed, as seventy-two per cent. When reduction

was easy, it was thirty per cent., and ninety-one per cent. when reduction was difficult. Hare, in his work, gives the mortality seventy-four per cent. when the cases were treated medically, and seventy-five and four-tenths per cent. where abdominal section was done. In most cases where abdominal section has been performed, the cases have been treated for quite a while by medical means and, of course, it does not give the surgeon a proper showing. I have no doubt if early operation was performed that the mortality would be much less.

The medical treatment consists in the use of opium and belladonna for the purpose of relieving pain and quieting perisstalsis, then endeavoring to overcome the intussusception by injections and insufflation. Injections should always be used early in the case. If it is deferred until inflammation occurs, until the intussusception becomes fixed, then I believe it is exceedingly dangerous, the danger being over-distension and rupture of the gut. The same thing will apply to the use of insufflation. Some authorities recommend that injections be used without anæsthesia, so that it can be told by the sensation of the patient when there has been sufficient water thrown into the bowel. At the same time they reccommend that insufflation be used under an anæsthetic with the patient in the inverted position. After a trial of these means for a short time with negative results, then operative interference ought to be instituted at once.

The best point of doing a laparotomy is in the median line. It is usually not difficult to reach the intussusception by this incision, but if this cannot be done, it is a very easy matter to make an incision directly over the seat of the tumor. Great care should be taken in overcoming the invagination; by pressure upon the gut you can empty it to a certain extent of its distended blood vessels, then by careful pressure upon the protruding portion from below, as was done in the case I operated upon, you can usually overcome the invagination without much difficulty, provided inflammation has not occurred and adhesion of the serous surfaces taken place. When this has occurred they may be broken up usually by the use of a probe.

Where we fail to relieve the invagination then it becomes necessary either:

First—To make a lateral anastomosis above and below the intussusception; or,

Second—To resect the affected portion of the gut and make an end to end anastomosis; or,

Third—To make an artificial anus.

The mortality is always very much greater where the trouble occurs in the young.

Cor Adiposum.

Schott (*Deut. med. Woch.*) observes that, although there are no certain signs of this condition, there are several symptoms, such as the general state of the patient, the condition of the heart sounds, rhythm, etc., which makes the diagnosis very probable. Often this fatty deposit in and about the heart cannot be distinguished from fatty degeneration. The author gives some account of the physical and dietetic treatment of the disease. The object of the dietetic measures is to diminish the amount of fat. There is no means of making collections of fat disappear from certain parts of the body. The fat round about the heart disappears last in starving animals. Thus the improvement in the patient's condition cannot be brought about in this way. Purgative measures are harmful, and the doubtful effects of iodides are often further obscured by other symptoms produced by them. If anæmia, diabetes, gout, and especially arteriosclerosis, be present, dietetic treatment must be adopted with great caution. Any considerable loss of weight must be carefully guarded against. Patients who have lost weight in consequence of treatment by mineral waters and dietetic restrictions may develop signs of cardiac weakness. As regards limitation of fluids, the amount of alcoholic beverages must be lessened. It is probable that the loss of weight which may occur when fluids are dimished is really due to the impaired appetite. The author's methods of treatment consists in methodical exercises, bath treatment, etc. He thinks his treatment may be carried out with benefit, and without the risks attending other methods reccommended. He quotes cases to show that unpleasant symptoms may be removed without the patient losing weight. It is only when the heart has gained strength and is not to be distinguished from a normal heart that any thinning treatment should be adopted. Any rise of temperature is also a contra-indication to it. Moderate exercise in the fresh air, which may be increased later, is useful, but over-exertion may produce unpleasant symptoms.

EDITORIAL.

NEGLIGENCE.

The physician, more than any other professional man, is sensitive to criticism. This is due, probably, to the peculiar characteristics and relationships of his profession, to the high standard of individual qualifications which must be attained to deal with the many complex issues involved in practice, to the varied and strong competitions with which he must contend, and to the jealousies with which he must combat—jealousies multiform in expression, sometimes creditable, generally discreditable.

Zeal for mastership in the profession grows with the ever widening domain of its science and art, and with the equally progressive intelligence of the people. Possibly this zeal receives no slight stimulus from the increasing difficulty of taking, in the character of a quack, refuge from the consequences of practice as a professed physician.

Diligence may justly be claimed as one of the salient merits of the great body of the profession; yet negligence may occur with the overworked physician as well as the underworked, indolent or indifferent, though for very different reasons. But errors and negligences are closely scrutinized and receive but little sympathy either popular or judicial.

The tests of what a man knows in his professed art or science may not be those of scholastic refinement, but the tests of his practice are chiefly those of the fidelity with which he applies what he knows; the simple tests of professional and moral duty. There is no continuous duty in which one can engage without, at some time or other during its discharge, becoming liable for negligence. By its very limitations, the human mind is incapable of perfect diligence. The chief danger is that diligence may become intermittant.

Two kinds of neglect must be borne in mind—negligence in commission and negligence in omission. The niceties of distinction between the two is of little moment here. It is the sequence, the mischievous consequences, the natural and probable results of the negligent act or omission that are of vital concern.

The legal liability of a physician comes under the same rules that govern in matters of the business expert generally. He is obliged in each case to apply such

diligence as good physicians, called under similar circumstances, are accustomed to apply. Negligence, as interpreted in civil relations, is an "inadvertant imperfection by a responsible human agent in the discharge of legal duty, as produces in an ordinary and natural sequence, a damage to another." The inadvertancy or want of due consideration of duty is the injury.

No general rules can be laid down as to what constitutes negligence. To make the physician liable, his negligence must stand in immediate causal relation to the injury. The diligence of the physician must be more than that of common-sense. It must be the diligence of science and skill. A person who, without special qualifications, is called upon to attend a sick person, is expected to apply such diligence only as is bestowed in such cases by persons of ordinary common-sense, and is liable only for failure in such diligence.

As a rule, the degree of diligence required is proportionate to the duty and responsibility imposed, and the degree of negligence imputed corresponds to the degree of diligence exacted. In each case, negligence is the failure to bestow the care and skill which the situation demands.

It is conceded that the negligence of the specialist varies with the nature of the specialty and the intensity of the duty. The skill of the specialist must be that which he usually employs ; he must show himself an expert in the particular branch with which his reputation associates him—if an oculist, he must show himself an expert in his specialty; he must exercise a greater amount of skill and care than is implied by the word ordinary. For a person without the necessary qualifications to undertake a business requiring skill, is itself an act of negligence, causing damage but not implying an intent to injure. The surgeon who undertakes an operation for which he has not the proper qualifications, is liable for the damages his unskillfulness works.

Diligence should extend to those having the care, nursing and management of the patient. Neglect of such often involves the physician in trouble. There may be no liability, yet culpability. But there exist not a few instances where legal liability has been found on the part of the physician, where there was mismanagement or neglect on the part of those having charge of the case. Cases of this character stand, by analogy, upon the same ground with a common class of cases—*e. g.* an action for the recovery of damages caused by alleged defects in highways. The liability of the town is established, the injury proved and the resulting effects become the subject of inquiry. Whereupon the town claims and endeavors to prove that, owing to mismanagement or negligence in treating the injured party, the consequences have been aggravated. Such showing on the part of the town does not touch the cause and right of action, but the measure of the damages only.

There may be negligence as to instructions needful to be given patients. It has been held by the courts that a physician who had attended a broken limb, was liable for injuries resulting from failure to give instructions as to the use of the limb after the patient's discharge.

A patient under treatment may injure himself, yet he may recover of the physician if the latter carelessly or unskillfully treats him afterwards, and thus does him a direct injury. It must be remembered that there are few ailments in which the patient may not be charged with more or less negligence.

There is a negligence that grows out of over-anxiety or of timidity. It is a factor in many accidents and injuries, and is a frequent cause of fatal results. Lord Macauley has illustrated this aptly:—"Queens, it has often been said, run far greater risk in child-bed than private women, merely because their medical at-

tendants are more anxious. The surgeon who attended Maria Louisa was altogether unnerved by his emotions. 'Compose yourself;' said Bonaparte, 'imagine that you are assisting a poor girl in the Faubourg Saint Antonio.' Bonaparte knew mankind well; as he acted toward the surgeon, so he acted toward his officers." Knowledge, skill, nerve, dexterity and diligence are the requirements.

It is good law, and sound reason as well, that more should be required of the specialist than of the non-specialist. He must put into his work what he professes to the world. It must show in his results. He must possess fertility in expedients, and promptness and intrepidity in applying the right remedy, at the right moment and in the right way, to the right thing.

As Mr. Huxley succinctly states it;—"There is really only one way of ennobling any calling, and that is to make those who pursue it really masters of their craft, men who can truly do what they profess to be able to do and what they are credited with being able to do by the public. And there is no position so ignoble as that of the so-called liberally educated practitioner who, as Talleyrand said of his physician, 'knows everything; *even a little physic*,' who may be able to read Galen in the original, who knows all the plants from the cedars of Lebanon to the hyssop upon the wall, but who finds himself with the issues of life and death in his hands, ignorant, blundering and bewildered, because of ignorance of the essential truths upon which practice must be based."

ABSTRACTS.

TUBERCULOSIS IN CATTLE.

[The results of investigations dealing with the serious question of tuberculosis in cattle from both economical and sanitary standpoints are embodied in an important report of the Agricultural Department prepared by Dr. Theobald Smith, chief of the Animal Pathology Division. The report in part is as follows:]

In making tests the temperature of the inspected animal should be taken every two hours, at least six or seven times before making the injections. The most convenient place for an injection is the side of the neck where the skin is thin, and a large strong needle gives much more satisfaction than a small, fine one. Seven or eight hours after the injection the temperature should then be taken, and from then on every two hours until a decided reaction, continuous during several hours, has occurred, or until eighteen or twenty hours have passed since the time of the injection. To attack tuberculosis as it exists at present, is a most difficult problem, and no single measure, however sweeping, is likely to be successful. The present wide dissemination of the disease, and its prevalence among other domesticated animals, as dogs, cats, horses, and, above all, its prevalence among man, makes the complete extinction of the malady an unrealizable problem. Infection through the air is the most serious problem to be dealt with. A question of such practical consequence is the effect of repeated infections. That cattle may be infected more than once is self-evident. The more frequent infections the more rapid the disease and the speedier the danger to other animals. The fewer the tubercle bacilli in the air, the more reduced the danger. It is highly probable that cattle may, under conditions, inhale a few tubercle bacilli without permanent injury. The importance of reducing the amount of infection in a herd by all possible means, and keeping it permanently reduced, is one necessary condition for the successful eradication of tuberculosis.

Primary infection through the air is more frequent under existing conditions than any other mode of infections; early stages of the disease may consist of glan-

dular affections only; extent and rapidity of the disease depends at least in part upon the number of tubercle bacilli inhaled either within short or long periods of time; tuberculosis of the lungs is not necessarily associated with any other recognizable lung affection as a pre-existing favoring condition. Tuberculosis of the liver is probably in most cases a result of food infection. Tuberculosis of the membrane seems to cause less damage to the animals affected. It takes place principally by escape of bacilli from some forms of the disease situated under one of the serum coverings, as lungs, liver, intestines and associated lymph glands. It does not appear probable that organs are invaded to any extent by tuberculosis starting on their serum covering. The tubercle bacilli appear to be usually carried in lymph channels with the current, but a case of evidently retrograde movement of the bacilli has been noticed. The virus of tuberculosis does not vegetate in the blood, its presence there being accidental. In the more advanced stage of the disease infection of the blood may occur repeatedly. Generalized infection may be recognized by the discovery of disease in organs not accessible to the virus in any other way than through the circulation or in the lymph glands of such organs. Tuberculosis of the subcutaneous lymph glands and of those situated in the muscular tissue of the trunk and limbs, is universally accepted as indicative of the generalized disease. Such glands may be infected from without, but infections through wounds in the skin are quite rare. Generalized infection, both chronic and acute, has obtained considerable attention owing to its important bearing on the infectiousness of meat and milk. In all cases of generalized disease the milk should be regarded as dangerous. The difficulty, from the practical standpoint, lies in the recognition of the generalized infection during life. With the meat the question is simple and resolves itself into thorough inspection of every carcass at the abattoir by trained inspectors, and with the living animal there are only a few guides, such as the conditions of the udder lymph glands or fragment of some superficial lymph glands.

The region of the throat and of the small intestines are more likely to absorb tubercle bacilli early in life than later on, while the lungs seem to become, with age, the preferred seat of the disease. Demonstration of this assumption is complicated by the fact that calves are more exposed to food infection than adult animals, because of the dangers of tubercle bacilli in the milk. There is every reason to believe that most of the tuberculosis of cattle is not demonstrated at or before birth, but is contracted by contagion later on in life. Cattle owners should pay special attention to the condition of udders, a disease which is particularly dangerous because the milk at first appears normal for some weeks, and, therefore, would be used with impunity. With this disease the only danger to other herds lies in direct contact or in the transfer of a diseased animal or of milk from such an animal. The greatest danger exists in the immediate surroundings of the infected and loses itself as the distance increases. In order to control any infectious disease it is of the utmost importance to recognize in the living animal not only advanced stages, but even the slightest infection. It is essential that the tuberculin test be repeated not later than after an interval of six months, so as to reveal cases not detected at the first test. Cattle owners should become familiar with the general nature of tuberculosis, thereby lifting themselves above the plane where quackery and specifics abound, and understand precisely what to expect after the disease has entered the herd, and how to meet the demands of public health. Sanitary precaution should begin the removal of diseased and suspected animals. The investigations show that the milk of tuberculous animals is not so frequently infected as supposed.

Milk of animals in the earliest stages of the disease, and with perfect udders, does not contain tubercle bacilli. Only those showing signs of labored breath and emaciation should be gravely suspected and their milk excluded at once from sale.—*Public Opinion.*

A NEW THEORY OF THE NERVOUS SYSTEM.

Every one knows that the nervous system seen under the microscope, whether it be a question of the brain or the marrow, consists of two principal elements. The first of these elements are the long fibers, the thin threads, placed side by side in great numbers and in a very particular manner. These threads appear to play the part of conductors: they connect the marrow to the brain, the different parts of the brain to each other, or they form the nerves, connect the muscles to the marrow, or place the latter in communication with the sensitive organs: the organs of touch, of the retina, of the internal ear, of taste, of smell. These threads serve to transmit shocks, vibrations, from one part of the nervous system to the other; they are like telegraphic wires which transmit the current from a distance; they are the advance routes, the roads of communication.

The elements of the second group are physiologically higher. They are composed of the nervous cellules. These cellules form the essential part of the nervous centers; it is the cellules which are met by the conducting threads, and the nervous cellules have from all time been considered as centers, as points from which are developed the modifications, the vibrations, of which the nervous fibers are finally made the vehicle. The nervous filaments have the form of threads; the cellules are little bodies of irregular form which, from their angles, send out a certain number of very fine fibrils. For a long time, histologists have been trying to find out the exact relation of the cellules with the threads and the cellules with each other. Not long since, an Italian, Golgi, gave us some very important information on certain sides of these questions. He discovered a method of coloring which permitted him to separate certain elements, so that some of them remained uncolored, and in this way he showed that the fine network of fibrils which surrounds each nervous cellule is furnished, not with a protoplasmic substance, but with elements of a purely nervous structure which are subdivided in proportion as they are removed from the cellule. There is a network of protoplasmic prolongations, but these are not connected with those of the neighboring cellules: they have a free termination, most often in the vicinity and in contact with the capillaries, and represent a system of roots, by means of which the cellule is nourished with the contents of the capillaries. They are not at all nerve conductors.

These views of Golgi at first created great surprise, for they made the cellule simply a sack of nutritive moisture. It must, however, be admitted that these views are exact. A Spanish scholar, Ramon y Cajal, has completed these experiments in a very comprehensive manner. He has furnished us with a very clear idea of the true relations of the cellules. Each of these forms an apparatus, giving birth to two orders of fibers. Some of these are centripetal or cellulipetal, and form a passage for the vibrations coming to the cellule from without; the others are cellulifugal, and serve as passage ways for the vibrations going out from the cellule. The first are the protoplasmic filaments; the second are the threads or fibrils of the nervous structure. The two elements of the network surrounding the cellule have then two different functions: by means of one the nervous vibrations arrive; from the other, they depart. But the principal fact made manifest by Ramon y Cajal is that there is no continuity between the two orders of fibers. Tne cellulifugal fibers of a given cell do not mingle with the cellulipetal fibers of a neighboring cell as was formerly believed: there is only proximity and contact. This amounts to saying that there is no fixity or immutability of the network of communication between cellule and cellule: a vibration does not necessarily pass by a pre-established way. This is of the greatest importance, not only from an anatomical point of view but still more and above all for psychology, heredity, education and conduct. It is a well-known fact that no first performance of anything is satisfactory. But in what does this work consist? In forming, establishing a way of communication. If the fibril network were fixed, if the ways were pre-established, work would be easy, and it would be difficult to comprehend why exercise renders frequent operations so easy to transmit until finally they become almost

automatic. But from the moment we find the ways are not fixed, and that they are only established by repetition and exercise in a more or less different manner for each individual, and that several ways may be formed, everything is explained. If the habitual way is obstructed, a new one may be formed; the vibrations take a different road, but reach the same goal. We then have an anatomical base for the well-known differences shown by different individuals with regard to the acquisition of any talent, no matter what. The capacities, the predispositions are determined by the anatomy of the structure, predispositions which may be purely physical, intellectual and even moral. We must then change our conceptions with regard to criminality and morality. We owe to the refactory elements of society more pity, more humanity, but we have less hope of drawing them from the condition in which we find them. I have only attempted to indicate the questions which are raised; but it is enough to show in what distant domains this work of Ramon y Cajal finds its echo.—*Henri de Varigny in the Paris Revue des Revues* in *Public Opinion.*

TREATMENT OF ACUTE AND CHRONIC ULCERS.

Dr. DeCourcey in the *Louisville Medical Journal* writes:—

I have found no classes of diseases yielding to treatment with greater reluctance than "old sores," or chronic ulcers. Recently, however, I have adopted a plan of treatment which is quite different from that laid down in the books, and my results have been much better.

Almost without exception, internal, or constitutional, as well as local treatment, is necessary.

The internal treatment should be directed to the seat of the malady, thus eradicating the general pathological condition, eliminating the poisons and disease germs from the system.

To accomplish this object, absolute cleanliness (internal and external), plenty of pure air and sunshine, the religious observance of the laws of hygiene, and a wholesome nutritious diet, are more useful and restorative in their effects than are drugs. All the secretory organs of the body should be required to perform, as nearly as possible, their natural amount of work.

This once accomplished, and all nature's machinery kept lubricated and in good working order, the local treatment and work of reconstruction will be comparatively easy.

The sores, ulcers, acute and chronic, must be kept clean. This is done very satisfactorily by the application of hot water. If the parts cannot be soaked in the hot water, an ordinary fountain syringe can be filled with water (as hot as can be borne without burning), elevated high enough to give sufficient velocity to the stream which is played over the parts by the operator holding the nozzle of the syringe a short distance from the seat of the application. The frequency of the washing will depend upon the nature of the case, but should be repeated as often as necessary to keep it clean and free from offensive odors.

To destroy pus and bacteria, and to aid nature in the work of rebuilding the parts invaded, I have found hydrozone and glycozone superior to any and all other agents tried.

Hydrozone is first applied (after the hot water) by the use of an ordinary glass dropper, or hard rubber syringe, slowly, all over the ulcer, until the pus is destroyed. Effervescence, or fermentation, continues until the enemy is quite dead, but no longer. One layer of absorbent cotton is saturated with glycozone and placed smoothly over the parts, and held in place by a cotton bandage, sufficiently tight to hold the cotton in place.

Other local medication might do as well in some cases, but I have not so found it. The result obtained in the case I report herewith, seems to confirm the statement as above made.

Edw. K., age twenty-three; American, but German descent; a farmer by occupation; unmarried; rather small in stature, but well-built; having taken sixteen bottles of "blood purifier" and a lot of "anti-constipation pills" within the last eight months for "falling sickness," came to

my office March 19th, with both legs most frightfully ulcerated, from knees to ankles, with considerable discharge of pus from various parts of the legs. Such a case should have been sent to a hospital or sanitarium for the best systematic treatment obtainable, but, unfortunately, he was so situated that he could not be sent to such a place. In a most pleading way he asked me if I could do him any good. I told him I thought so, if he would mind me, and take the treatment that I should advise. He promised, and the treatment was begun.

The legs were cleansed by soaking them for twenty minutes in hot water twice a day, after which hydrozone was used freely all over the sores, to destroy the pus, the pustules having been opened and as much pus evacuated as possible.

After this application, morning and evening, the legs were powdered all over the affected portion with a mixture of equal parts of alum, boric acid and aristol, then covered with absorbent cotton, and bound up with an ordinary cotton gauze bandage.

This local treatment was kept up for two weeks. The improvement was slow, but constant. The process of healing advanced from the knees downward and from the ankle upward, leaving the last part to heal about the middle of the leg, where the ulceration formed a thick crust, extending two-thirds around each leg.

The constant discharge of pus from the sores caused the dressing to stick to the parts, which could not be removed without difficulty.

The alum, boric acid and aristol powder was discontinued and glycozone used as a reconstructive agent, from the end of the second week. The sores were washed and the hydrozone used as before mentioned, then the glycozone was applied to the whole affected parts. A layer of absorbent cotton was saturated with glycozone, and smoothly placed around the sores, and held in place by a cotton bandage.

There was not any further trouble about the bandage adhering to the sore. The granulation was much more rapid than at first. At the end of the next week the results were very gratifying. At the end of the second week after hydrozone and glycozone were used as the sole local agents, the young man said he was well, and worked every day from that time.

The internal treatment was changed from time to time as the case required. Opiates were given several times during the first two weeks of the treatment, to ameliorate the pain, which was very great at times. He was much emaciated and melancholy when he first came to me. His bowels would not move without cathartics.

Fluid extract nux vomica was given morning and noon, seven drops before each meal. Elixir lactopeptin, with bismuth, was given in drachm doses after each meal, and, occasionally, laxatives at night. Later on, tincture chloride of iron was given, in ten drop doses, after each meal, for one week.

After the third week no internal treatment was given, as the patient was in good condition, happy and cheerful.

Hydrozone and glycozone were left to complete the structure, and to place upon it the capstone of a beautiful new integument, which they did in a way gratifying both to the patient and to myself.

Infantile Diarrhœa.

Ewald prescribes:

℞
Benzonaphthol .....
Bismuth, subnit.....
Resorcin.....ää gr. iss

M. Sig.: For a child 1 or 2 years old one such powder every two hours until six have been taken.

Dr. Comby sometimes orders

℞
Naphthalin..... gr. xv
Pulv. sacchar..... ʒiiss
Ess. bergam..... gtt. v

Mix and make into 20 packets. From 5 to 10 packets daily, according to the age of the child.

It may be given thus (Baginsky):

℞
Naphthalin..... gr. iss
Calomel..... gr. i-6
Pulv. sacchari..... ʒv

M. Sig: For 1 packet. A child 2 or 3 years old may take 5 or 6 packets during the day.

Dr. Filatow relies upon

℞
Naphthalin..... gr. ij
Bismuth. subnitr..... gr. ij½

M. Sig.: For 1 packet. One such packet every two or three hours for a child of 2 or 3 years.

THE PAY OF PHYSICIANS AND SURGEONS.

The physician is generally sure of a good living, but he must work hard to gain it. The incomes of professional men can be estimated only in an approximate way. Since the amount of money earned is considered by the public as a measure of appreciation of services rendered, there is a strong tendency to give as facts what should be, rather than what actually is. Physicians form no exception to this rule. The average annual income of a physician in full practice in a large city may be stated as $2,000, and in the smaller towns and in strictly rural districts $1,200. Two or three physicians in New York make over $100,000 each year; five or six range from $50,000 to $60,000; fifty from $25,000 to $30,000; one hundred and fifty from $10,000 to $12,000; about three hundred from $5,000 to $6,000; fifteen hundred from $2,000 to $3,000 and the remainder from $800 to $1,000. When we endeavor to estimate the average income of the doctor, we must consider many controlling influences which bear upon his work. When he begins practice, his income will probably range from $800 to $1,500 per annum.

Payment for medical services varies in different localities. In the large cities the fees are always comparatively higher. But even in New York the charges are not extravagant. The general family practitioner charges from $2 to $5 per visit to the patient's house. The average of such fees for the wealthy is $5, although twice that sum is usually demanded by practitioners whose practice is mostly limited to that class. Office consultations by experts range from $10 to $25, as do also consultation visits. Visits out of town are from $10 to $20 for each hour of absence from home, plus traveling expenses, and the regular fee of $25 for the consultation itself. Surgical operations command the highest prices, and also range according to the skill and fame of the operator, from $100 up into the thousands. Night calls are twice the amount of day calls, whether ordinary or consultation visits. While all this is true of the established practitioner, the younger men must be content to take one dollar in their offices. In many of the smaller towns the physician gets no more than half a dollar for an office visit, and but twice that for a call within a mile from his home. Those physicians who confine their practice to a special branch make larger incomes than those who do a general practice. But when we take into account the long preparation necessary, the special studies that must be made and the time spent in attaining proficiency and reputation, the difference in the end is not so great as might at first be supposed.

The pay of the profession in different countries averages about the same when the relative cost of living is taken into account. The fees in Paris for surgical operations run from $200 to $5,000. Except that the latter sum is not infrequently paid, there is no difference as compared with American or English rates. Still there are only three or four surgeons in Paris who can command such prices, and only two who are reputed to make $100,000 a year. The Parisian fee for a surgeon called in consultation is $20, whether in his office or at the house of the patient. The consulting physician receives somewhat smaller pay, the amount ranging from $12 to $20 per visit, while at his office it is from $4 to $10. The highest annual income of a French physician is $40,000, although the late M. Charot is reported to have made much more. The general practitioner in Paris averages $2 per visit, but in aristocratic circles he demands $4. Allowance must also be made for smaller living expenses in Paris than in London or New York. In comparing our fees with those of the German physician and surgeon it is well to understand that, although a German mark is reckoned as equivalent to twenty-five cents, its purchasing value in Germany equals our dollar here. Thus the German family doctor, while he nominally gets but 2 marks for an office visit, can really count on $2 of actual worth to him. The specialists of Berlin and other large German cities charge from 5 to 10 marks for outside calls. The first-class medical authorities, who are necessarily professors in the universities, charge 20 marks in their offices and 30 for house visits. All other things being equal, we can count the average earnings of the German family

doctor to be about 5,000 marks, and the consultant's and professor's income 10,000 marks.

The late physician to the Prince of Wales received for four weeks' attendance at Sandringham, during the illness of his distinguished patient from typhoid fever, not only the usual title of baronet, but a fee of £10,000. Sir Morell Mackenzie is reported to have received more than twice this amount for his treatment of the late Emperor Frederick of Germany. His Royal Highness the Nawab of Rampur, India, recently paid an English army surgeon £50,000 for a three-months occasional attendance in an ordinary attack of rheumatism. This is said to be the largest fee ever paid for medical services in that so-called heathen country. The late Sir Andrew Clark, Gladstone's physician, often charged $1,000 for running down from London to Liverpool, and the late Sir William Gull commanded equally high rates for similar services. A Russian surgeon charged a wealthy notable of Odessa $6,000 for opening an abscess of the hip, the time occupied being about ten minutes. And better still, while on the same visit, he took a chance shot at another patient in the shape of a similarly simple operation, for which he received nearly $1,500 more. But in all this it is not so much the doing as the knowing how to do. When the French peasant said that there were not ten francs' worth of paint on Rosa Bonheur's "Horse Fair," he was incapable of valuing high art. "Five dollars for amputating the leg," said the surgeon, "and nine hundred and ninety-five for knowing how"—and the victim was thankful accordingly.—*Dr. George F. Shrady, in the Forum for September.*

THE BUBO PLAGUE IN CHINA, WITH A BRIEF ACCOUNT OF THE GREAT PLAGUE OF LONDON.

BURNSIDE FOSTER, M. D.

The first extensive epidemic of the plague, of which history has recorded any definite account, occurred in the sixth century, A. D., and is usually described as the Plague of Justinian, since it existed during nearly the whole of that emperor's reign.

Although there are some discrepancies in the various accounts which I have consulted, the epidemic seems to have had its origin in Lower Egypt in the year 542. From its starting point it traveled up the Nile, and then leaving that stream it swept with increasing fury into the interior of Asia Minor. Constantinople was visited, with the result that for some days the people died at the rate of 10,000 daily. In the next year it traveled over Greece and Italy; in 545 it extended into Gaul and in the following year reached the cities of the Rhine. During the seventy years of its existence this fearful disease visited all the parts of the known world and its victims were numbered by millions. In several instances historians have recorded that more than half of the population of many of the cities, perished, and that scarcely people enough were left alive to bury or destroy the bodies of those who died.

During the succeeding years of the Middle Ages we have no knowledge of any very extensive plague epidemics until the sixteenth century. In the year 1500 it raged in Germany, Italy and Holland for seven years; in 1534 in southern France; in 1562 for six to eight years it was pretty general throughout Europe. During these epidemics we find it recorded for the first time, that to some extent epidemics were considered preventable, and that there were attempts at disinfection and insolation. Sulphur, arsenic and alcohol were among the earliest disinfectants; and the plague physicians, "Pest Medici" as they were called, wore special gowns and masks and anointed their hands and arms with medicated oil before coming in contact with the sick. During this and the seventeenth centuries a number of severe and fatal epidemics of this dread disease occurred in all parts of Europe, but the one of which I will make special mention is the Great Plague of London which occurred in the year 1665.

De Foe's "History of the Plague," and

the "Works of Dr. Thomas Sydenham," a very eminent physician of that time, give from their different points of view, such a comprehensive and interesting account of the events of that dreadful year that I shall quote from them both in some detail:

In September, 1664, there began to be rumors in London that the plague was again raging among the Dutch and in the latter part of November two men said to be Frenchmen died of the plague in a house at the upper end of Drury Lane. During the next few months there were occasional cases in the same part of the city, but it was not until early in the following May that there began to be any serious apprehension. With the warm weather the cases became more numerous and in the second week in June about one hundred died of the plague in the out parishes and the disease began to appear in the city, and by July 1 the pestilence had become so general that business of all kinds was suspended and many of those who had the means to do so shut their homes and places of business and fled to the country. The panic among the people became so great that many went mad through fear and others deliberately committed suicide to avoid the infection.

De Foe records that the posts of houses and corners of streets were plastered over with doctors's bills and papers of ignorant fellows quacking and tampering in physic and inviting the people to come to them for remedies.

"Infallible, preventive pills against the plague. Never failing preservatives against infection. Sovereign cordials against the corruptions of the air. Anti-pestilential pills. Incomparable drink against the plague. The only true plague water. The Royal Antidote against all kinds of infection, and such a number more that I can not reckon up, and if I could would fill a book of themselves to set them down."

Others assuming specious titles summoned people to their lodgings by such bills as these:

"An eminent High Dutch physician, newly come over from Holland, where he resided during all the time of the great plague last year in Amsterdam and cured multitudes of people that actually had the plague upon them."

"An ancient gentlewoman having practiced with great success in the late plague in this city, Anno, 1636, gives her advice only to the female sex."

"An Italian gentlewoman, just arrived from Naples, having a choice secret to prevent infection, which she found out by her great experience, and did wonderful cures with it in the late plague there, wherein there died 20,000 in one day."

"There is no doubt," says De Foe, "but these quacking sort of fellows raised great gains out of the miserable people, for we daily found the crowds that ran after them were infinitely greater, and their doors were more thronged than those of Dr. Brooks, Dr. Upton, Dr. Hodges, Dr. Berwick, or any, though the most famous men of their time."

The Lord Mayor and Aldermen adopted very sensible and very stringent measures for the separation of the sick from the well, and for general disinfection, which doubtless had a considerable effect in controlling the disease. An infected house was at once shut up and a watchman appointed to guard it day and night, to see that none entered or left it without special permission. By this means, harsh and cruel as it was in many instances, the infection was to some extent confined and localized. During August the deaths became so numerous that it was impossible to give decent burial to the bodies. Great ditches were dug, and the bodies, without discrimination were cast into them. It was estimated that above ten thousand houses in London were deserted and that about two hundred thousand people left the city. From August 8 to October 10, according to the mortality bill there died in London 59,810 people, of whom 49,605 died of the plague, The total number of deaths from the plague during the epidemic is placed by De Foe at 100,000. From November 1 the number of cases began to diminish, the death rate of those attacked became smaller and as winter came on, people returned to London, resumed their business and by February of the next year the great plague was over.

In regard to the nature of the infection by which the disease is spread, De Foe, after discussing various opinions says: "Others who talk of infection being carried through the air only, by carrying with it vast numbers of insects and *invisible creatures*, who enter into the body with the breadth or even at the pores with the air, *and there generate, or emit acute*

poisons, or poisonous ovæ which mingle themselves with the blood and so infect the body." Strange that the actual discovery of germs and of the ptomaine theory should have been delayed for two centuries!

The symptoms of the disease are thus described by Sydenham:

"Its first approach is almost always accompanied with shaking and shivering like the fits of an ague; presently violent vomiting, a pain about the region of the heart, a burning fever with the usual concurrence of symptoms perpetually afflict the sick till either death itself or a happy eruption of a bubo discharges the morbifick matter and so frees them from that deplorable condition. It does now and then happen that it comes without any sense of fever before and suddenly kills men; the purple spots which are the forerunners of death breaking out as they are about their business. But this sudden death scarce ever happens but at the beginning of a dreadful plague. It sometimes also happens that swellings appear when neither a fever nor any violent symptoms went before. The victims sometimes died within a few hours of the first symptoms, and rarely lingered beyond four or five days. If the buboes suppurated it was considered to be a favorable circumstance and they were therefore treated by incision or by caustic."

The other local manifestations were carbuncles, furuncles and ecchymoses. A peculiar and characteristic stench was omitted from the bodies of the sick. At the beginning of the London Plague upwards of 90 per cent. of those attacked, perished. Towards the end of the year the disease seemed to have become milder and the mortality was much less.

I have gathered from various sources a pretty accurate description of the epidemic now devastating China, and its identity with the above is undoubted.

The disease first appeared in the Province of Kwantung in the latter part of March and spread principally among the poor and filthy, with frightful rapidity. More than half a million people perished in two months and the groat commercial centers, Canton and Hong Kong, were soon attacked. In the former with a population of 1,000,000, the number or deaths exceeded 100,000!

The symptoms are thus described: With or without premonitory warning in the shape of malaria or chill there is a sudden onset of fever, rising to 105° F. or over; there is much headache and cerebral disturbance accompanied by stupor. In from twelve to twenty-four hours glandular swellings occur in the neck, armpits or groin, rapidly enlarging to the size of a hen's egg; these are hard and exceedingly tender; with or without a decline of the fever the patient sinks into a deeper condition of coma and dies usually at the end of forty-eight hours or sooner. If six days are reached recovery is hopeful. The glandular swelling shows no signs of suppuration, in some cases epistaxis or vomiting of blood occurs. Petechiæ appear in a few, but there is no regular eruption. The mortality is about 90 per cent.

In the latter stage of the disease, when the local manifestations are most apparent, the fever usually diminishes and their occurs a sticky and very offensive perspiration. The inguinal and femoral glands are those most commonly affected, although those in the axilla and neck are often involved at the same time. The carbuncles are of less constant occurrence than the buboes and are usually seen on the lower extremities, the buttocks and the back of the neck. Among the sequelæ in those who finally recover, are continuous suppuration of the büboes, abscesses of the skin and muscles, pneumonia, dropsy, partial paralysis and mental disturbances.

The malady is undoubtedly a filth disease and caused by a bacillus. Indeed, Professor Kitasato, a competent bacteriologist and a pupil of Koch, claims to have discovered the specific germ. There is no doubt and it has been repeatedly demonstrated during the last one hundred years that efficient quarantine gives absolute protection from the disease, and that modern sanitary means can rapidly stamp out an epidemic should a few cases be imported into a well ordered community. It has been well named, "the disease of barbarism," from the fact that it only occurs among the semi-civilized. There is little to be said concerning treatment. There is no known specific and the treatment, like that of all acute fevers, must be supporting and symptomatic. Should there be given sufficient opportunity to study this disease scientifically, which is not at all likely, I am convinced that the only specific medication would be found in the development of the antitoxin theory. It is also probable that immunity might be given by inoculation of an attenuated virus.—*Jour. Amer. Med. Ass'n.*

SOCIETY REPORTS.

LOUISVILLE MEDICO-CHIRURGICAL SOCIETY.

May 4, 1894.

[STENOGRAPHICALLY REPORTED BY C. C. MAPES.]

ABDOMINAL TUMOR—CONTINUED REPORT.

DR. A. M. CARTLEDGE: This gentleman, Mr. H., was before the society one month ago for examination because of an abdominal tumor. The concensus of opinion at that time was that the spleen constituted the tumor. Some days afterward I did an exploratory section and the trouble was found to be the liver which is displaced, with a number of adhesions around it, showing evidences of several attacks of circumscribed peritonitis. The adhesions were carefully separated, but the liver was, of course, not raised to its normal position. In the light of second knowledge, it is very easy to demonstrate the situation of Mr. H's liver; he has no liver in the normal site. It has not been quite four weeks since the operation, and his recovery from it has been uneventful.

I believe there has been great relief. He says he feels much better; the liver has decreased very much in size, being now almost normal except its situation; his complexion has also improved very much.

DISCUSSION.

DR. T. S. BULLOCK: I saw Dr. Cartlege perform the exploratory laparotomy on this man; in fact, I was the anæsthetist, and he called my attention to the situation of the tumor, and its appearance. It could be demonstrated at first glance that there was absence of the liver in its normal situation, and its presence in this abnormal position—a dislocation of the liver.

DR. A. M. CARTLEDGE: Mr. H. has been examined repeatedly by some of the brightest and most eminent doctors, as he says, in several States, and no one even suggested that the trouble might be the liver. It has been diagnosticated various things, but the correct diagnosis was never made until after the exploratory incision.

DR. J. W. IRWIN: I recollect that I examined this gentleman when he was presented by Dr. Cartledge before the society on a former occasion. I am very glad that the doctor brought the case before us again to-night and corrected a very grevious error. It seems reasonable that any man should be able to tell by percussion whether there was dullness in the region of the liver or spleen, but this case seems to be one that has misled—so to speak—a great many. At the previous examination his abdomen was more tympanitic than it is to-night; there was not any very marked dullness over the region of the spleen, in fact hardly any, and there was perhaps not quite so much over the region of the liver; yet there was some defined dullness. However, the case was hardly one that would be considered in a perfect state for examination, the abdomen was very tympanitic at that time, neither was his position from necessity such as we would like to have. But this illustrates a very important thing—how ready we are to give opinions without making a thorough and careful investigation of the case. I believe I am among those who stated at the previous examination that there was practically no dullness over the region of the spleen, and can only account for it as I have stated.

DR. TURNER ANDERSON: It is the most remarkable case that I have ever seen presented to a medical society. I have never before seen a case where the liver was in the left iliac fossa.

DR. A. M. VANCE: I examined this man when he was before the society on a former occasion, but did not make any diagnosis. The case illustrates the fact that we ought to be very careful and go slow in making our diagnoses in such cases.

DR. T. S. BULLOCK: I was present when several of the members percussed

this patient's liver, and although Dr. Cartledge stated when he presented the case that there was a suspicion that it was a displaced liver, he was not certain until he made the exploratory incision. I listened while Dr. Marvin and several others percussed the region of the liver at the first examination, and thought I detected the normal dullness of the liver, and was very much surprised to find when exploratory incision was made, complete absence of the organ in the normal situation. Dr. Cartledge at the operation demonstrated to his own, and to the satisfaction of every gentleman present, the absence of the liver in its normal site; he demonstrated the lobes of the liver and the gall bladder in the abnormal position, and there can be no question about its being a displaced organ.

PARALYSIS FACIALIS.

DR. W. O. ROBERTS: Two weeks ago this young man while driving in a dog cart, his horse fell and he was thrown out striking his head on the pavement. He was unconscious for fifteen minutes. After regaining consciousness he was taken home in a carriage, and had considerable hemorrhage from the ear. Then hemorrhage kept up, not continuously, but at intervals, for forty-eight hours; there was not succeeding the hemorrhage any watery discharge from the ear. Tuesday following the accident facial paralysis was first noticed. I had him come here to-night because I thought it was a case that would be of interest to the specialist. He evidently has either a fracture through the temporal bone involving the canal through which the nerve passes, or a clot, or inflammatory product. The accident occurred in Friday and facial paralysis developed the following Tuesday. All that was done in the way of treatment was during the time the hemorrhage was going on, the ear was thoroughly irrigated with hot water with a view of stopping the blood. Since then it has been frequently irrigated, because, while there was little or no discharge from the ear, it was quite offensive. Dr. Ray has examined the case and can tell us the condition in which he found the canal.

DISCUSSION.

DR. J. M. RAY: Dr. Roberts kindly asked me to see this patient on Wednesday following the accident. I examined first his ear by the speculum; found the roof of the canal had been pushed down. The surface of the drum membrane was covered with blood which had become dry. There was no discharge from the ear. As far as his hearing powers were concerned, air conduction was destroyed but he could hear the turning fork by bone; this I think demonstrates the fact that the internal or nervous portion of the ear is not involved. Therefore there is a fracture probably extending through the roof of the canal and through the membrana tympani into the roof of the middle ear, involving the Fallopian canal. The question of course comes up as to whether the paralysis is due to fracture and pressure by a spicula of bone upon the nerve, or wheher it is due to hemorrhage. The prognosis to a certain extent also depends upon that. I have seen several cases of this kind which recovered very promptly. Fractures through the temporal bone are, I think, quite common in head injuries. Dr. Vance will recall a case that we saw some time ago. I reported the case at the time and looked up statistics on the subject and found there was quite a variety of opinion, some authorities claiming that the fracture did not involve the roof of the middle ear unless there was escape of the cerebrospinal fluid, others claiming that frequently there is no escape of fluid. Buck reports cases where there was no escape of fluid and very little hemorrhage. Fractures through the middle ear cavity and even fractures about the base, are quite frequently overlooked. I have seen several cases of head injuries where there was paralysis of different muscles; Dr. Vance will remember the case of a child I saw with him where there was paralysis of the sixth nerve from head injury, and at the same time enomous retinal hemorrhages. The child recovered very promptly.

DR. S. G. DABNEY: It would seem to me that from the paralysis coming on three or four days after the injury, the case should be regarded as more hopeful. If there was a fracture and pressure of a spicula of bone on the nerve, we would naturally expect paralysis to have taken place immediately, Ruptures of the drum membrane from falls or blows on the ear are not rare. This spring I saw one produced by a snow

ball hitting the ear. I have seen several cases similar to the one shown to-night, but without the facial paralysis; I do not remember to have seen one having that feature. I remember one case resulting from a child sliding down the bannisters, falling at the bottom and striking the head. There was unconsciousness for sometime and later there was quite a free discharge of blood, without any watery discharge from the ear. There was a rupture of the drum membrane with some disturbance of gait, and later some disturbance of sight of the same side. Taking into consideration the disturbance of sight led me to make an ophthalmoscopic examination in that case, and I found the retinal veins of the corresponding eye considerably engorged. All the symptoms disappeared in a few weeks, the drum membrane healed, and the hearing was good though never quite perfect.

DR. WM. CHEATHAM: It seems to me that what Dr. Dabney says about the case shown by Dr. Roberts is about correct. The paralysis coming on so late leads me to believe that it is most likely from swelling and not from pressure of a spicula of bone. My experience has been in these cases of paralysis that they get well but that they are a long time doing so. I have seen them as long as three years making a satisfactory recovery, especially where the eye muscles have been involved. In a great many cases there is some general disease of the nervous system, which should be taken into consideration in making a prognosis.

DR. TURNER ANDERSON: I associate this case with Bell's paralysis, the result of trauma very similar to the conditions that we observe in forceps application where the momentary depression of the mastoid process is such as to permit undue pressure upon the nerve as it passes through the canal.

DR. J. W. IRWIN: Two or three years ago I saw a boy sixteen years old who had been struck by a sixteen pound iron ball on the frontal os; he was knocked senseless. I saw the patient five hours after receipt of the injury and he had some bleeding from the ear, followed by a straw colored discharge—serum. There was no paralysis attending the injury. I think very likely in Dr. Roberts' case the diagnosis is correct, and I believe the trouble is due to inflammatory effusion. Whether there is a fraction or not, no one can tell.

DR. H. A. COTTELL: About the only question arising in the case is the location of the hemorrhage; the probabilities are that the trouble is due to pressure upon the facial nerve the result of inflammatory action as Dr. Anderson suggests. It is possible, however, that the condition is purely hemorrhagic. You can indulge in almost any number of theories as to the cause, but one thing is certain, there is pressure upon the nerve in the Fallopian canal. I should say the prognosis is favorable in such a case; about as favorable as it usually is in Bell's palsy. It is well-known that Bell's palsy is originally a traumatic palsy. The way the disease came to be called "Bell's palsy" was by virtue of the fact that Sir Charles Bell attempted to relieve a very severe facial neuralgia (before the function of the fifth and seventh nerves were discovered) by incising the seventh nerve. This produced complete paralysis. Bell's palsy was therefore originally a traumatic palsy. We know that in ninety-nine cases out of a hundred of Bell's palsy, (paralysis of the facial muscles) the trouble is in the Fallopian canal; the facial nerve in going from the internal auditory meatus to the stylo-mastoid foramen traverses a certain part of the petrous portion of the temporal bone, and any trouble—be it congestive, traumatic, inflammatory or whatever it may be—causing pressure upon the nerve in that region will produce what we call facial paralysis. If all the muscles are involved, we know that the trouble is peripheral; if there is involvement of only a few of the muscles, we know the trouble is central. The majority of cases completely recover. In the case before us I should incline to make a favorable prognosis, but I believe electro-therapy is indicated in the case.

Dr. W. O. Roberts presented a report of

LAPAROTOMY FOR RELIEF OF INTUSSUSCEPTION; WITH REPORT OF A CASE OCCURRING IN A CHILD AET. NINE MONTHS.

(See page 428.)

DISCUSSION.

DR. TURNER ANDERSON: Dr. Roberts has reported the case so fully that there is really nothing left to be said. I saw the

patient one and one-half hours before the operation. The child when first seen presented the unmistakable physiognomy of a serious illness, that was simply all. It was being carried around the room upon its mother's arm and would occasionally manifest evidence of abdominal pain, but was not screaming; except for the pinched appearance of the countenance, I would scarcely have recognized that the child was more seriously ill than when suffering from an ordinary attack of colic. But the history of the case was important; the child had been ill four days under the care of a very excellent medical practitioner. He had suggested the day before that an operation be performed, and I am satisfied had made (although I do not know positively) a diagnosis of the condition. Diagnosis of the case was not difficult; the abdomen was not especially distended, in fact there was very little tympanites, but there was a sausage roll extending from the region of the sigmoid flexure upwards for about four or five inches, and at variable intervals the child would manifest considerable discomfort and straining. Upon inspecting the rectum there was no difficulty in detecting the protruding mass just within the sphincter, which, as Dr. Roberts has said, came out after the child was partly under the influence of the anæsthetic, possibly two inches through the sphincter muscle. I had the child suspended by the legs and introducing my finger into the rectum I could press up the invaginated portion, and at first I pressed it so far that I hoped it had been returned. I could feel all the way around it, could dilate the gut to such extent as to make the diagnosis complete. It began at the cæcum, passing through the colon, carrying with it the vermiform appendix and pulling down the smaller bowel as it descended through the large bowel and rectum to the anus, so that when it was relieved the last portion to come out was the cæcum and the appendix. The cæcum and appendix were so enlarged and œdematous that had they been seen at first there would have been a suspicion that the trouble was malignant in character. In other words, the morbid processes had extended to such an extent as to at first sight make the condition questionable.
